Hi Cecil,

I see you still live in a dimensional aberration where you experience
22 days as 66 minutes. You must be oxygen starved by now.

Yaesu puts a chart in their G1000 manual that spells this out. Don't remember the exact numbers, but with the antenna 8 feet above the rotator I think you were limited to something like 1/10 the normal specification. I wouldn't go more than a foot above the rotator.

Barry, W9UCW has done extensive measurements using termocuples and other methods minimizing disturbance to measured system. He found that current in (esp. longer) coils is diminishing towards the other end.
If you read the thread and some more velleyball on Topband reflector last month, there is more info.

My point is that if the output impedance really was at a perfect
50 Ohms, then using a perfect 50 ohms transmission line, you can never
match to anything other than 50 ohms.

If the S22 is something other than 50 Ohms (usual case), then a
transformation via 50 ohm coax about a constant VSWR is possible, for
the purposes of matching to a not-quite-perfectly-50 ohms antenna.

Egad.

Given only a line's characteristic impedance and the load impedance, I can tell you exactly what the SWR is for a lossless line. For a lossy line, I only need to know, in addition, the line's length and the amount of loss per unit length. In no case do I need to know the source impedance.

If, as you insist, the source impedance affects the SWR on the line, please provide an equation that gives the SWR on the line, with source impedance being one of the variables. It's such a simple thing, surely such an equation appears in one of the several references you cite. I did notice that SWR doesn't appear in any of the titles or the quoted passages, though, so you may have to dig a little.

And if Cecil's work leads to the conclusion that the source impedance impacts the line's SWR, then it's wrong.

It is, for those who are interested, very easy to see intuitively why the source impedance doesn't affect the SWR. Consider the situation that occurs when the source is first turned on. A forward voltage wave travels down the line toward the load. A reflected wave, whose magnitude and phase are determined by the reflection coefficient at the load end of the line, returns. If we stop time just as the reflected wave is returning, we can calculate the SWR, so far, on the line, solely from the ratio of the forward and reflected waves -- it's the interference between these waves that create the standing waves. Turning time back on again, the returning wave reflects off the source (assuming a source mismatch), producing another forward wave. Let's watch this wave as it travels toward the load, reflects, and returns. Exactly the same proportion of this wave is reflected as for the original forward wave. So, when this new forward wave reflects and its reflected wave returns, we've got a total of two forward waves and two reflected waves. The forward/reflected ratio of the second pair is exactly the same as the forward/reflected ratio of the first pair -- it's the reflection coefficient at the load end. So the ratio of the total forward wave to the total reverse wave is the same for the first pair, the second pair, and the sum of the two pairs. In other words, the second pair of waves hasn't changed the SWR from what we calculated from the original pair of waves. You can continue this observation for each forward-reverse pair, and see that the SWR never changes (at least when observed when each reflected wave just returns) from the original value. And the original value was determined only by the load mismatch, not the source. The source mismatch determines how big the total forward and reflected waves end up being when all the reflections have died out to a negligible value. But it has nothing to do with the forward/reverse ratio, which

determines the SWR.

Sorry, it's not clear from what you've said just what you're trying to match to what.

Truly, if you connect a 50 ohm load (be it a resistor, or some impedance transformed by a transmission line, tuner, or other means -- makes no difference) to a transmitter, and the transmitter's output impedance isn't 50 ohms, there will be a mismatch at the transmitter output.

But who cares? Most transmitters are designed to work properly when terminated with 50 ohms, but that doesn't at all mean that their output impedances are 50 ohms. And it certainly doesn't affect the SWR on any transmission line connected to the transmitter. If you were to discover that your transmitter's output impedance were, say, 10 ohms and you connected it to a 10 ohm load, you'd have a very unhappy transmitter. All you have to worry about is presenting the transmitter with the load it was designed to work into, not what the internal impedance of the transmitter is.

Thank you Richard,
the PIN diodes they choose are UNITRODE (by now TI) UM4010 with a
resistance of 0.17 OHM and a maximun back bias voltage of 1000 V
(2000V breakdown voltage). The current handling capacity is 10A at an
ambient Temp of 70 degree C. You are right this thing had to be
expensive and you need about 5 or 6 of them. I couldn't find anything
on this device on the TI website, probably obsolete.

Hm, I've used WD-40 on everything from 115 VAC power switches to VHF slug-tuned inductors, potentiometers, and relay contacts. Whatever conductivity it might have, hasn't been a problem for me. I wouldn't use it on 100 meg level impedances, but more from worry that it would pick up dirt and grunge.

What sort of experiment can you suggest that will demonstrate and perhaps allow measurement of its conductivity?

If you add 1/4WL to the top of the antenna, the current in the coil
will *increase* towards the other end. In a standing wave antenna, the
total current is the sum of the forward current and the reflected
current. Whether the total current increases or decreases depends
on the phasing of the two currents at the point where the coil is
placed.

The calibration of the SWR meter is controlled by the internal sampling load resistor, the 'R' in Peter's V + IR equation. I have a home-brewed SWR meter that measures SWR on both balanced 450 ohm feedlines and on 300 ohm feedlines simply by changing the internal load resistors.

3030. G5RV 450 ohm or 300 ohm Phasing line

Newsgroup: rec.radio.amateur.antenna

From: Andy <dx90@blueyonder.co.uk>
Message-ID: <xOd_a.246$rp.66@news-binary.blueyonder.co.uk>
Source record: 110773

Hi all

If I choose G5RV Half or full size antenna what is the best phasing line to use and why 450 ohm or 300 ohm. I will be using a internal ATU on my transiever.

If I go for the full size G5RV I will have to use the first 66 feet straight harizontal up at 30 feet and the last 36 feet at a right angle sloping at 45 degrees, will this work ok?

Thanks

Andy

Hi Roy,

Your crafted requirement reveals the shortfall inherent in the
problem. It is distance based too, and without that discussion there
is no way to forecast what SWR or Power reading you would obtain from
simply knowing both the load and source's Z's. This is why it is
called Mismatch Uncertainty.

I have provided NBS and NIST documents both recently and in the past.
Recent offerings are obscure, as I have already admitted. The earlier
citations I provided were direct and to the point and serve as the
basis of the recent work. I have provided data that exhibits the
effect. I have provided the test protocol in how to achieve that
data. I have also described that this data is also, theoretically,
achievable through standard interference math also presented by me in
the past.

It takes little imagination to observe that there is a zone of
confusion that lies between two reflecting interfaces when the path is
not fully described. My data showed that path in one foot increments
of transmission line over an interval of a quarter wavelength or more.

We have been offered evidence of this Mismatch Uncertainty by Dr.
Slick if I am to trust his postings - be that as it may, because it
requires no further proof.

Simply put, bald assertions that SWR is unaffected when read between
two discontinuities is wrong without a concomitant description of all
paths leading to the SWR meter. This is a commonplace of interference
plain and simple. I have observed no one describing this detail
(except Dr. Slick).

As all this is part of the historical record entitled:
"The Cecilian Gambit, a variation on the Galilean Defense revisited"
I do not see how its repetition here brings anything new to the mix.

None the less, this recent example has been fun. :-)

When I got a new vehicle I replaced my Hustler system with an Outbacker Perth. I did this because the Outbacker makes such a nice neat installation that does not attract a lot of attention. It works well for me but I mostly operate on 20-10. I really can't tell any difference on these bands versus the Hustler.

It's not just theory, it's practice and measurable. But it's not a requirement that loss introduce reactance to Zo; it's just that if the line is lossless it must have a non-reactive Zo. Clearly if L/C = R/G, the impedance will be non-reactive.

Also, consider what reactance you do get in practical lines, at what frequencies. What effect does frequency have on the reactance? Why? Under what conditions will it really be a problem? Might the reactive part be so small that it will be totally swamped out by variations in the real part? Think a bit about how much it will or won't mess up the measurements you want to make.

Cheers,
Tom

Dunno about using PIN diodes to switch turns in a helix for an
antenna, but for sure they are used as TR switch elements to some
rather high powers. The usual switch topology turns on two diodes
during transmit so that there is little RF voltage across either, but
certainly they can work fine with P-P RF voltage up to their reverse
breakdown voltage, which can be hundreds of volts. (Some 1N4007s are
actually PIN structure, for example.) They can be put in series to
stand off more voltage if necessary. Just takes a very low current DC
bias voltage at half the breakdown.

I believe the HF radio used in P3 aircraft after they decided that the
ARC-94 didn't have enough frequency stability and resolution had an
electronically-switched tuner which I suppose used PIN diodes.
Perhaps some lurker knows for sure. That was quite a long time ago.
There are probably bunches of examples of power switching which also
require voltage standoff since then.

Cheers,
Tom

It's admittedly hard for me to follow what you've written, but it sounds like you're saying that:

1. Source impedance affects line SWR, and
2. It's impossible to tell by how much.

Did I get that right?

Incidentally, you've brought up a new topic, that of an SWR meter. My original statement said nothing about an SWR meter; it dealt only with line SWR. As Reg and other have pointed out many times, an SWR meter reading is often very different from the SWR of a connected line, so it has no direct bearing on this discussion.

>
>Did I get that right?
No. The sources offered and the data exhibited provide a very clear
answer. To state this yet again, it is the lack of knowledge in the
distances traversed between reflecting interfaces that introduces the
Mismatch Uncertainty. A smart lad might conspire to present any
particular Power measurement if he could withhold other details from
scrutiny. A lad who considered himself smart may do the same but
think he invented a free power amplifier (or dissipationless load).

This is simply an account of poor boundary controls that turn some
folk into magicians and others into the reincarnation of Galileo.
Either outcome is achieved through delusion.

>Incidentally, you've brought up a new topic, that of an SWR meter.
Look at the Subject line.

As for the aside about SWR meter reading, I have performed SWR
measurements with a variety of NBS methods (many hundreds of times) -
none of them described here very often, and some never at all. I
doubt any here are so well versed in these methods as to challenge my
data by employing them (it would only confirm the results). I would
be happy to see as much effort put to it - in that it would represent
a technical rebuttal rather than echoed denials. I would be happy to
retract my points if someone revealed an error of commission/omission
- such has not happened and discussion of that data has been wholly
absent.

Look Roy, skip the rhetoric (from all sources including me) and
explain or refute the data I obtained. If you cannot accept it,
reveal the error. If the method is too tedious to replicate - say so.
This is not the first time I've broached the subject and I certainly
don't expect many to care for one, or follow blithely for another. It
only matters in issues of accurate Power determination.

3045. Magnetic Loop Experiences

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-13 00:23:18 UTC
From: PMac <vk2evb@nella.net.au>
Message-ID: <3f3984fa@usenet.per.paradox.net.au>
Source record: 110789

Hi, I am in an area with a fairly high manmade, powerline noise and interference level. I am thinking of building a magnetic loop for 160, 80 & 40 metres and was hoping that it would not be so susceptible to the above types of interference. Also the antenna size factor appeals to me but comparisons with a dipole are hard to find. Any comments appreciated.

That sounds reasonable.
Including physical properties of the coil (Length/diameter ratio, physical size) in the calculations of the model could help to optimize the system, allow more precise calculations and participation in the optimization routines.
If the load is treated as point, the current is considered the same at the entrance and exit of the coil, which is not the case especially in longer loading coils. Question is to what extent is program capable of capturing and then massaging it and what is the correlation to real life situations.
I got some RF ammeters, it will be interesting to see wasaaap.

3048. Coax Cable vs Freqency

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-13 00:40:34 UTC
From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <bhc1e1$oo0$1@hercules.btinternet.com>
Source record: 110792

For anyone who may be interested.

Typical of RG-58 and RG-11 type cables.
Zo = Ro - jXo
Xo is always negative.
Angle of Zo in degrees. Always negative.
VF = relative velocity.

Freq	Ro	jXo	Angle	VF
50 Hz	967	-965	-44.95	0.034
1 kHz	220	-213	-44	0.151
10 kHz	80	-58	-36	0.41
100 kHz	56	-9.3	-9.5	0.59
1 MHz	52.4	-2.4	-2.7	0.63
10 MHz	50.7	-0.76	-0.86	0.65
100 MHz	50.2	-0.23	-0.27	0.66

Smith Chart calculations begin to be inaccurate around 2 MHz and below. So do SWR meters.

Only one bad thing about sending hunters out with guns for animal population control. They dont take out the weak and those of poor genetic quality. They tend to take those from the top of the herd. Only restoring the balance of predatory animals will really solve the problem. BTW I am a deer hunter.

I stated that the source impedance has no effect on the line's SWR. You said that was incorrect. I can (and happily will, on request) present equations which one can solve for SWR without any reference to the source impedance, as well as an explanation for why line SWR is independent of source impedance. You have presented some reference titles and many interesting words, but not an equation that shows the dependence of the source impedance on SWR. Nor any reason why it should.

I haven't seen your data, but if it shows a dependence of SWR on source impedance, then I certainly refute it, and believe you should closely examine your methodolgy. Your references notwithstanding (which don't obviously deal directly with SWR at all), widely accepted theory and equations universally support my statement. Therefore, if your data show the contrary and you're certain they're correct, you're in a position to rewrite currently accepted principles of electromagnetics. But sorry, I don't feel it's an appropriate use of my time to find flaws in measurements that contradict established theory.

I stand by my statement.

The scale is calibrated using known loads so yes, it displays the
correct SWR up to 5.83:1. Above 5.83:1 the resolution of the scale
is poor because the full scale SWR is infinity. I have marks at
5.83:1 and 10:1. 5.83:1 is where the reflected power equals half
the forward power. Incidentally, the Z0 of my '450' ohm ladder-
line is closer to 388 ohms.

Cecil,

Would these be the termination resistors to ground, one for each
directional coupler? I would think that you would have to adjust the
width of the traces as well, or the thickness of the dielectric
material, or the space between the couplers and the thru-line to use
it for an impedance other than 50 Ohms (talking about commercial
equipment, that is).

Those mobile antennas are standing-wave antennas. The forward current is relatively constant and is reflected at the end of the whip. The reflected current adds to the forward current to give the total current. A standing-wave antenna is similar to a transmission line with standing waves except that it is designed to radiate and the transmission line is not. The major reason that the current drops through the loading coil is the same as for a 1/4WL monopole without a loading coil. The total current is maximum at the feedpoint and drops to zero at the end of the whip because the forward and reflected currents add to those values. The forward current through the coil is virtually the same value at each end of the coil. The reflected current back through the coil is virtually the same value at each end of the coil. The phasing between those two currents is what determines the total current which is indeed different at each end of the coil.

I use a toroid to sense the RF current and an R=Z0 resistor to turn it
into a voltage. I have a capacitive voltage divider on the RF voltage
which is adjustable for calibration purposes. The only real difference
between it and a 50 ohm SWR meter is the internal load resistor. It's
actually a bridge circuit with a Z0 reference resistor. Unfortunately,
it is not very accurate for the relatively high SWRs that I run on my
ladder-line, e.g. 4:1 to 16:1

True. Never considered this before, thank you. Makes sense that
if the ratio of the series resistance and shunt conductance are the
same as the ratio of the series inductance and shunt capacitance, that
the transmission line will still be non-reactive.

In general, using an MFJ antenna analyzer to get a rough idea of
what the series equivalent complex impedance is (these are not $80,000
vector network analyzers!), it seems that cheap 3' RG-8x jumper coax
cables mainly add series inductance to the system, as the reactance
gets higher with increasing frequency.
We try to design 9 element chebychev low-pass filters, which is
not difficult at very low power levels, as two 1/4 watt 100 Ohm
resistors make a decent dummy load all the way out to 200 megs or so.

The problem is characterizing insertion loss using higher power
transmitters, when we know that the 1000 watt cantenna swings from 40
to 70 Ohms (with reactance too) as you get above 80 megs or so. It
become difficult to know if you are moving in the right direction or
not.

I have a bunch of 50W 600 ohm non-inductive resistors that I use
for calibration purposes. And I really don't know the accuracy.
An SWR of 20:1 looks the same as an SWR of 25:1 on the scale.
I have an upper and lower acceptable limit to the SWRs with the
matching method I use. The SWR meter tells me if the SWR is
outside of that acceptable range.

As you might know, the input S11 or SWR will change when you go
from an antenna analyzer or network analyzer to measuring with the
actual full power PA and meter hooked up. This may be partly due to
the fact that the meter is usually not a perfect 50 ohm thru, and
partly due to the fact that the analyzers outputs are closer to 50
ohms than the PA.

If I understand the point you are trying to make, you are stating
that the perfect 50 ohm SWR of a system will never change.

However, keep in mind that you CAN normalize the Smith Chart to
have anything be in its center, like 10 ohms or something.

And i don't think you can expect the measured SWR with the meter
and PA to be exactly the same as what you get with a small-signal
analyzer. It's usually a bit different.

If S11 or the SWR actually does change, you've either got a nonlinear transmission line or a nonlinear load. That is, the impedance changes as the signal level changes. If you *measure* a different SWR or S11, it means that either the SWR or S11 is actually changing for the reasons I just stated, or the meter is nonlinear in the sense that its reading changes with power level (possibly due to RF ingress, but it could be a host of other things), or you're measuring with two different meters that don't agree.

It's not because of the different source impedances.

Sure, you can normalize a Smith chart to anything you'd like. That doesn't make the SWR change with source impedance.

>outside of that acceptable range.

It's interesting to see an example of an SWR meter for a Z0 that isn't 50 ohms, because it helps to confirm that they all work in basically the same way.

If [V] is a sample of the line voltage, and [I] is a sample of the line current, then the forward reading is the sum of two RF voltages, [V] + [I]R, where R is the resistor that converts the [I] sample into a voltage.

The reverse reading is the difference, [V] - [I]R. The "calibration to Z0" procedure consists of terminating the line in the design value of Z0, and then adjusting R so that the reverse reading [V] - [I]R is zero.

The RF voltages are either summed or subtracted, and then the resultant is detected by the diode.

Just one small point, though... it is not necessary that R = Z0. The value required depends on the sampling factors kV and kI that relate the voltage and current in the line to the sampled values [V] and [I]. In full, the instrument is calibrated to Z0 when:

kV*V - kI*I*R = 0

In a typical bridge, two out of the three constants kV, kI and R are fixed, and the third is adjustable. In a Bruene bridge, kI is fixed by the number of turns on the current-sampling toroid, R is fixed, and you calibrate the bridge by adjusting the kV factor in the voltage divider. However, it would be equally good to build-in fixed values of kV and kI, and balance the bridge by making R a small trimpot. So R really does not have to equal Z0... and in most published circuits, it doesn't.

This can also be shown in a different way, by thinking of it as a Wheatstone bridge, with Z0 as one arm. The requirement for balance is only that Z0/R2 = R3/R4. It is not necessary for any of the other resistors R2, R3 or R4 to equal Z0 in order to achieve balance.

AFAIK, the only situation where the "terminating" resistor truly needs to equal Z0 is in parallel-line couplers for microwaves, when the sampling line approaches a quarter-wavelength long and its own characteristic impedance is Z0 too.

That is no phasing line. You use a phasing line when you want to feed
two or more antennas in or out of phase. You will only have one
antenna.

I will be using a internal ATU on my
> transiever.

It might work ok, but I'd be careful. Those tuners in the radios are
not really that well suited for this type of use. It will probably
tune, but keep an eye out for possible tuner overheating with large
mismatches. I always prefer an outboard tuner when tuning a ladder
line fed antenna. If it were me, I'd run ladder line the whole way. No
coax.

Sorry, that is exactly wrong. S11, SWR and the impedance itself, do
not change when you connect a different instrument to the same load.
All the changes you have described are due entirely to instrument
errors.

That's how the instrument errors are determined... by knowing for a fact
that, whatever all the different instruments may say, the impedance
they're trying to measure is the one thing that has *not* changed.

Tried that already and had no luck. I found two in this area. We couldn't get the first one apart after we laid it down (someone welded the bolts) and the other fell apart as we took it down (heavy rust).

As described in a previous message, there isn't a lot of room for guy wires. The area is about two and a half feet wide - just enough room for a cement slab to support a small freestanding tower. After that, there just isn't any room to run guy wires out very far. What there is (the building and a nearby fence) isn't going to provide a strong support for guy wires.

I agree with the first paragraph. However my experiences with loops (receive only for now) show a tremendous improvement in S/N for loops mounted right at ground level over dipoles mounted along the roof line. If you raise the loop, the signal improves further. Loops are something definitely worth investigating in noisy situations.

You are right, but i never stated that the impedance we are
feeding ever changes, only the measured SWR.

Hey, we live in the real world, with real instrument errors. This
is the case i am talking about when i started the thread. I usually
DON'T measure the same SWR from antenna analyzer versus PA and meter
hooked up, and this may be due to the fact that the PA has a different
source impedance than the analyzer. I'm not claiming that the
impedance we are feeding has changed. And if you read my original
post, you will notice that the SWR didn't change when the coax length
was changed, mainly the incident power.

How would you explain what Cecil wrote? How are some people
improving SWR by changing coax length, when in theory they shouldn't
be able to do this?

Do you think the series reactance a system offers a PA may
actually improve it's incident power?

I disagree on this point. You are caught up in the 50 Ohm world,
which i admit is easy to do. The SWR is based on the ratio of the
forward to the reflected power. If you had an analyzer that was
calibrated to 20 Ohms (the same as normalizing the Smith for 20 Ohms
in the center) you would certainly have reflected power and high SWR
going into a 50 Ohm load.

And a 20 Ohm load would have a 1:1 SWR.

I'd just stop at the grocery or hardware store and pick up a can of
Brasso. Shined up my old brass military buckles very nicely, and
should do a fine job on whatever metal your antenna is made of.

It removes the corrosion very easily with a rag, and doesn't harm the
skin.

On second thought, i believe we are all wrong to equate S11 with
SWR!

Input S11 of a system will certainly never change. But the SWR
is absolutely dependant on the source impedance. If you had a network
analyzer calibrated for 20 Ohms, you would certainly have reflected
power and high VSWR going into 50 Ohms, and a 1:1 SWR going into 20
Ohms.

This would be the same as re-normalizing the Smith Chart for 20
Ohms in the center. You certainly can do this in MIMP.

I don't blame anyone for believing it's a 50-Ohm-only world!

Actually, the viscosity (the number indicates viscosity, not weight or density) is important. The lower the number the better. That's one of the reasons transformer oil is better for transformers and dummy loads than drug store mineral oil - it has lower viscosity. The lower the viscosity the more easily convection currents transfer heat from the dummy load into the fluid and from the fluid to the can. That means lower thermal resistance, giving a lower resistor temperature for a given power dissipation.

Brian,
I have no wish for a fight.....

My responses were to the initial question,

"Can motor oil be used " and the correct answer is a
qualified YES

If you want to leave a KILOWATT active overnight then I
would certainly say NO.
I certaily would recommend the Teflon coated cans since
can seams can sometimes 'weep'when thin oils are used.
If viscosity is your main concern then additional
circulation methods will alleviate that in a way far
superior to that using the best known transformer oil
(ARRL shows a method of achieving this)
If resisters are your main worry
then use a couple of wire resisters with the windings
oriented in opposite fashion since absolute accuracy is
intended for real dummies.(Note resistors change value
over time even when not in hostile environments.)
Check the values on an old tube/valve reciever for yourself)
As a point of interest, have you considered what creates
the first point of failure, and why transformers housings
are built so mechanically strong ? Can you tell me at what
time the 'flash point ' comes into play when considering
it.s use for a dummy load ? These questions go to the very
point that I discussed i.e using industry methods as
pointers BUT with due reference to the different environnments
and duty cycles required with respect to cost and availability.

Regards
Art

A shallow concrete slab will not support any tower unless the tower is
well bracketed to the house. There are only two choices: A large block
of concrete for the base or a slab with a house bracket.

> After that, there just
> isn't any room to run guy wires out very far. What there is (the building

Use a mast made from steel pipe. I've used 'em several times, works
fine. Assume the bottom section of the mast is made from a full length
of standard 2.5" Schedule 40 galvanized steel pipe x 21 feet long. Top
the base section with a couple 10-12 foot lengths of smaller diameter
pipe and assemble the mast & antennas. Drive a five foot length of 3"
pipe into the ground, clean it out, raise the mast to a vertical
position and drop it into the 3" pipe. Bracketing might be optional
depending on the load vs. the stress & deflection calcs. No concrete
and only a few square inches of real estate req'd in either case. Will
not be "light" and the pipe will cost several hundred dollars.
Aluminum pipe would be 40% lighter but would be considerably more
expensive.

The actual conceptual SWR and the difficulty in measuring the SWR are two
different things. Low power level SWRs are difficult to measure because
of the diode voltage drops. Better to use a class-B amp for such where the
zero-crossing points are aligned.

Oh dear... just when I thought it was safe to go back into the waves...

[On the other points, I'll reply to your second, corrected, posting.]

> How would you explain what Cecil wrote?

Who else but Cecil would dare attempt that? :-)

> How are some people
>improving SWR by changing coax length, when in theory they shouldn't
>be able to do this?
>
There are two possible reasons. One is instrument error - SWR meters are
not perfect.

The other possible reason is that the *outer* surface of the coax has
currents on it, so it has become part of the antenna. In that case,
changing the length of coax is not only changing the length of feedline
(the inner surfaces of the coax), but also is changing the antenna
itself. The voltage and current distributions on all the wires will
shift around, resulting in a different V, I and relative phase at the
top of the coax - in other words, a different feedpoint impedance. Then
the SWR (as measured on the *inside* of the feedline) genuinely will
change.

This SWR change is usually quite difficult to predict, because you
didn't mean there to be any current on the outer surface of the coax in
the first place. The only practical way to see if there could be a
problem is to use a clamp-on RF current meter to see how much surface

current is present.

If the SWR changes with feedline length *and* you have significant surface current, then you know one probable reason... but in all cases, these can also be instrument error in the SWR meter.

> Do you think the series reactance a system offers a PA may
>actually improve it's incident power?

To answer your exact question: I don't think there is a valid general answer. It depends on the specific PA design, and also on what you mean by "improve".

What I do know is that changes in the load impedance presented to a PA will change several of its operating conditions, all at the same time. Some of those changes will be "improvements" - but others definitely won't be.

For example, reducing the load impedance will usually make the output device operate in a more linear way... but the efficiency drops and the greater heat dissipation and current are likely to shorten the lifetime of the device. Is that an improvement?

> The RF voltages are either summed or subtracted, and then the resultant
> is detected by the diode.

I know you know this, Ian, but let's make sure that everyone understands that the summation (or subtraction) is a phasor (vector) summation. It is the phasing between the total voltage and total current that allows the forward wave to be separated from the reflected wave, and vice versa. The directional coupler designer assumes that the ratio of Vfor/Ifor = Z0 and that the ratio of Vref/Iref = Z0. If that assumption is incorrect, the SWR meter will still assume that the assumption is correct.

> Just one small point, though... it is not necessary that R = Z0.

That's true and is just a habit on my part. I set R=Z0 and then adjust the voltage accordingly for calibration purposes. For awhile, I was using a 450 ohm load for ladder-line with a measured Z0 of 388 ohms. It still worked pretty well.

> AFAIK, the only situation where the "terminating" resistor truly needs

> characteristic impedance is Z0 too.

In most of the slotted line pickups that I have seen, the internal load resistor is equal to the Z0 of the slotted line. I don't know if that is necessary or not.

Not if the feedline has a Z0 of 50 ohms. The problem would be in believing
what you believe about what the 20 ohm SWR meter is trying to tell you.

It is trying to tell you that it is being misused but you are inferring
that it is trying to tell you the actual SWR. It is not.

> And a 20 Ohm load would have a 1:1 SWR.

Not if the feedline has a Z0 of 50 ohms. If a DC voltmeter gives an
erroneous reading for RF voltage, do you blame the voltmeter or the
user of the voltmeter?

The impedance for which the SWR meter is calibrated is NOT the
same thing as the source impedance. If you are using an SWR meter
calibrated for 20 ohms in a 50 ohm environment, you are misusing
the SWR meter.

No! SWR, S11, return loss, rho, Y-parameters, Z-parameters, etc, etc are all different derived functions of the same two variables: an arbitrary complex impedance, and the system reference impedance Z0 (a constant which may or may not be defined as complex).

Only those two variables are involved, so all of these functions are locked together. If one variable changes, all the derived functions change too. Either all change, or none change; nothing else is logically possible.

As Roy says, the equations relating any one of these parameters to any other are all well known. NONE of them ever involves source impedance.

No argument about any of that... but it's a totally separate point that has no relevance whatever to your earlier statements about source impedance.

Source record: 110739

Non-linear, or time variant. I'd expect some variation going between
low and high power with typical dummy loads, because the resistance
will change with temperature. In fact, the loss in the transmission
line will change with temperature, too, and it's significant enough to
be able to measure with ham-type equipment if you are careful. But
I'd FIRST suspect other things going on: different calibrations
between different instruments, and the fact that SWR meters that use
uncompensated diode detectors will not read the same SWR at low power
as at high: they will fail to read high enough at low powers.

The resistance of the copper in the transmission line changes with
temperature. If ambient is 20C and you put in enough power to heat up
the line (center conductor) to 70C, that's a 50C change, and will
result in about an 18% increase in resistance. So if you had a line
which had 3dB loss at 20C, it would increase to about 3.5dB at 70C.
If the load end has a 2:1 SWR, then the sending end will have about
1.40:1 SWR at 20C and about 1.35:1 at 70C. It's not a _big_ change,
but it should be observable on an SWR meter that is accurate over a
wide range of powers.

I want to make it clear that this is in support of what Roy and Ian
are saying, as an added detail, and not contrary to the notion that
SWR on a line in a linear, time-invariant system with steady-state
excitation does not depend on the source impedance.

Cheers,
Tom

Get it out of the back of my truck! I got it in a package deal and have little or no mechanical ability. Will take almost anything on trade (except ham stuff as I'm not a ham. Locals know me as The Battery Guy.)

Here's a link for pics on the generator:

http://f1.pg.briefcase.yahoo.com/bc/thedeuceguy@sbcglobal.net/lst?&.dir=/My+Photos/Genset+for+sale&.src=bc&.view=t&.begin=1&.order=&.done=http%3a//f1.pg.briefcase.yahoo.com/bc/thedeuceguy@sbcglobal.net/lst%3f%26.dir=/My%2bPhotos/Genset%2bfor%2bsale%26.src=bc%26.view=t

On further exam of the engines, both are missing a small downdraft carb but otherwise look like you'd have the parts from one to repair the damage to the other. from the tags on the engine it would appear to have just been rebuilt in '93 and then damaged, maybe by a forklift, and then scrapped. Most damage seems to be to the coolings shrouds.The oil looks brand new and the engine and gen turns (the spare engine does not, but I did not have much leverage).

4 cylinder engine, also have an extra engine. Cage a little bent up, Not for the faint of heart but would make a very nice genset if you know what you are doing. I will consider trading for almost anything (NO recreational pharmaceuticals please). I got this genset yesterday as part of a package and am keeping the little genset. I'll trade for a gun (maybe with some cash for the right one), a 21" monitor, a cruiser type bicycle or mountain bike, heck, just about anything!

> On second thought, i believe we are all wrong to equate S11 with
> SWR!

(Of course they are not equal, just related by a formula [which is
usually stated slightly incorrectly])

If your reference impedance for measuring S11 is not the line
characteristic impedance, it's true that SWR = (1+|S11|)/(1-|S11)
won't give you the right answer. But then you haven't really measured
the reflection coefficient on the line, if you've used the wrong
reference impedance, since reflection coefficient is _defined_ as
reverse voltage divided by forward voltage. All this is right at the
heart of why I've been telling you that you should make sure your SWR
meter is calibrated to the impedance you think it is, and in
particular, to the line impedance (or close to that) if you really
want to know the SWR on the line. On the other hand, knowing measured
S11 and the reference impedance for it, and the line characteristic
impedance, you can determine the SWR on that line. But your "SWR"
meter isn't really an S11 meter; at best it's a |S11| meter.

This also brings up another point: do YOU define S11 to be the same
as reflection coefficient?

Cheers,
Tom

Cecil,
The most important aspect of all this is, if it is accepted
what would be the new emmission standards in Industry?
I can imagine a lot of users of RF driers will be happy
with the minimising of restrictions as well as other
manufacturers and users of such equipment.
Medical costs will also rise since equipment
used will now have to face new challenges.
The FCC got into hot water very quickly with their last
actions with Congress which also raised the ire of many others.
I doubt that they would be willing to follow the path of money
on this one because the cost related to required determinations
thru out Industry will fall on their own department.
They must also realise that numbers DO count with Congress since
looking after the Countries interests is NOT the first priority,
personal re-election is ahead of EVERY thing.
Haven't seen any statistics yet as to why Japan threw out the idea
or the timing of the same proposal in the U.K./EEC.
If the ARRL is so desparate for money maybe a short term membership
scheme would be in order, say $2 for a years subsciption to QST
without the last 2/3 s of the publication being offered!
Regards
Art

> not.

So if you have 200 feet of RG-213 and 200 feet of RG-58, put those in series to the cantenna. Coil them loosely and cool them with a fan if needed, if you are running high power (or start the chain with larger coax). That should get you close to 15dB attenuation in the coax at 100MHz and a 1.02:1 or better SWR at the input end for a 2:1 SWR at the cantenna. At lower frequencies where the line loss is lower, the cantenna is good enough that you don't need the line loss as compensation. Do I have you worried about what the actual impedance of the coax is from earlier postings? If so, good! Now you're in a position to think about what's good enough, and measure what you have to see if it meets the desired goals.

If that's all too kludgey for you, go buy a good load. Or just tune the cantenna for bands of interest. You could make a set of small boxes with L networks, each of which compensates the cantenna on a particular band. Or look up one of the articles about how to make a better "cantenna", probably starting with the parts you have. There are lots of options. Why settle for a setup which will only lead you deeper into confusion? Short of really precision measurements, there's a lot you can do trading off time and careful thought for the high cost of commercial equipment.

Cheers,
Tom

> coax). . .

One thing to keep in mind when you use coax as an attenuator or dummy load is that the portion of the cable nearest the transmitter dissipates most of the power. If you had, say, 6 dB per 100 ft attenuation and a 200 ft cable, the first 50 ft dissipate 1/2 the power (and that's concentrated toward the transmitter end), the next 50 ft dissipate 1/4 the power, the next 50 ft 1/8, and the final 50 ft 1/16. So do as Tom says and put the heavier coax up front, and allow for more air circulation for the coax nearest the transmitter if dissipation becomes a problem.

> of its electrical or physical properties?

1) Build, beg, borrow or buy a decent wattmeter and dummy load of the
characteristic Z of the cable.

2) Connect the output of your rig to the dummy load through the cable
to be tested. Put the wattmeter between the rig and cable to be
tested. Measure power on the highest band.

3) Move the wattmeter so that it is between the cable to be tested and
the dummy load. Measure power on the highest band (don't change
anything else!)

Difference is loss at the highest band when matched. A little math
will give you the answer in dBs.

In my example, the SWR on the ladder-line is not changing (except for losses in the ladder-line). Changing the length of the ladder-line changes the 50 ohm SWR meter *reading*, i.e. it changes the impedance seen by the transmitter.

That's true for a one-port load but not usually true for a two-port
impedance discontinuity in the transmission line.

> This also brings up another point: do YOU define S11 to be the same
> as reflection coefficient?

S11 is the (physical) reflection coefficient when a2 equals zero. When
a2 is not zero, the physical reflection coefficient, S11, will not usually
equal the measured reflection coefficient, the square root of Pref/Pfwd.

Dr. Slick wrote:
> . . .
> How would you explain what Cecil wrote? How are some people
> improving SWR by changing coax length, when in theory they shouldn't
> be able to do this?

The observation that changing line length changes the measured SWR is regularly reported in this newsgroup, and the explanation is as regularly provided.

There are at least three ways this can happen.

1. The SWR meter is designed for an SWR that's different from the line impedance. It's easy to show that this will result in different readings for different line lengths. I've measured RG-58 at over 60 ohms characteristic impedance, so this can happen even with a perfect 50 ohm SWR meter and "50 ohm" line. In this case, changing line length isn't really changing the line's SWR, just the meter reading.

2. There's significant loss in the cable. In that case, the longer the distance between the meter and the load, the better the SWR.

3. There's current on the outside of the coax. This means that the outside of the transmission line is actually part of the antenna. When you change its length, it changes the effective length of the antenna, which really does change the SWR. Current on the outside of the cable can also get into a poorly shielded SWR meter and modify its reading.

And this is all in agreement with established theory. So you see, theory does say you can change the SWR reading, and in some cases, the actual SWR, by changing the coax length. But only under very specific circumstances. When observations don't match theory, chances are overwhelming high that either the observation is erroneous or misinterpreted, or theory is being misapplied.

Hi Roy,

Such a study in peer review.

My correspondence in this thread replies directly to the subject
offered, and presents confirmatory evidence of the original author's
observation. I have presented method (before this thread was started)
that matches the author's problem. I have presented authoritative
sources that predict such behavior. I have presented data (again,
predating this topic) that conforms to those sources. I have
presented reason (long established theory) which explains the genesis
of the original author's predicament:
"The limits of uncertainty are obtained by evaluating
(1 ï¿½ |SourceGamma| |LoadGamma|)ï¿½
since SourceGamma and LoadGamma are complex
quantities."

You may find simpler expressions, or formula, that provide a neater
solution in the face of a matched source; but this does not answer the
subject line above.

That is the mismatch uncertainly between a source impedance and a load impedance.

SWR on a transmission line connecting the source and load impedance is a totally separate quantity, determined only by the load impedance and Z0. (Z0 may be defined as either the line impedance, or the system reference impedance; either definition is valid, provided you state which one you're using and calculate accordingly).

(And always in a linear, time-invariant system, as Tom points out...)

That's not correct. The SWR (more correctly VSWR) is, by definition, the ratio of the highest to lowest voltages which appear on a line long enough to have both a maximum and minimum. It can be calculated from the forward and reverse voltage waves. ISWR, the current standing wave ratio, is numerically equal to the VSWR.

If you had an analyzer that was
> calibrated to 20 Ohms (the same as normalizing the Smith for 20 Ohms
> in the center) you would certainly have reflected power and high SWR
> going into a 50 Ohm load.
>
> And a 20 Ohm load would have a 1:1 SWR.
>
Loads do not have an SWR, only transmission lines do. The fact that you get a reading on an SWR meter when it's connected to a resistor doesn't alter that.

You have to realize that an SWR meter isn't really measuring SWR, as Reg has repeatedly pointed out. It's actually measuring an impedance, and reporting that on a scale marked SWR. So you have to be careful to avoid making the mistake of confusing an SWR meter reading with the SWR on a cable it's connected to. The two correspond only if the cable's Z0 equals the SWR meter's.

Likewise, you have to realize that you don't change the SWR or "reflected power" when you change the normalization of your network analyzer or Smith chart. Those things are a function only of the load and transmission line impedance, not on your measurements or calculations.

For all of you that don't think the interferance is going to be "not so bad" even in CW, should come to Dayton, Ohio or any other city that still runs electric trolly lines and listen to the S-9 +40 signal that the 400 hertz trolly lines produce, and you can here it on a mobile reciever up to 2000 feet from the lines, especially when a trolly is in the area and moving. It cost money to fight the big money in DC, the power companies have an almost unlimited purse into which we the consumers have to keep pouring cash. They can hire the most costly lobbiest groups around for their cause. I run CW, PSK, RTTY and SSB here and it will really wipe out any and all signals on all bands, especially in wet and foggy weather, you guys better think again about simply bashing the ARRL about wanting money to fight this, or just sell your rigs now and buy stock in the power companies that will be polluting the RF spectrum from DC to Daylight with a bunch of noise that sounds like a geiger counter gone nuts in an uranium deposit. If the power companies get their way HF amateur radio will cease to exist as we know it. As I said, come to Dayton for the Hamvention next year and I will challenge you to do any HF work any were near an elelctric trolly line. Or just drive near any high tension power line and listen to the S-9 + noise levels from them, and with no broad spectrum data streams on them yet. The power companies have the FCC chair in their pockets guys and the power companies won't lift a finger now to clean up their act. What do you think they will tell you when BPL wipes out you Ham radio and other RF spectrums. You guessed it, they will tell you to go away and shut up as the FCC says that they have the right to do it.......

3121. 2m 9 Element Tonna

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-13 23:21:54 UTC
From: John <john@vhfdx.idps.co.uk>
Message-ID: <3f3ac755_2@mk-nntp-2.news.uk.tiscali.com>
Source record: 110765

Do the 2m 9 element Tonnas have insulated reflectors/directors or are they electrically grounded to the boom?

Thanks

John, G1ARI

Still either ground the mag mount to the vehicle or don't ground the rig,
otherwise you have a situation that I have run in to myself a few times,
with the ground on the rig and not on the antenna mount the SWR was out of
sight, with both grounded, or both ungrounded the SWR was just fine.

Are you saying that the antenna system, with the ground wire connected, looks ok with an analyzer but not the rig's SWR meter? If so, I'd guess that the ground wire is causing a current that's getting into the rig. You might try putting out four or so wires spaced evenly around the car, each to its own ground rod, to force the current to flow more or less symmetrically from the antenna base downward, as it was without the wire -- if that's practical. There are also some things you could do to isolate the rig from stray currents, such as putting common mode chokes on the feedline and power wires, and possibly isolating the rig from the car chassis. But that might be more trouble than it's worth.

And I've used WD-40 in and around ignition components on several
engines and fired things up a LOT better than with the water that
was previously there.

I suspect WD-40 conducts no better than white kerosene.

Agreed. Then any mismatch loss from PA to the 50 ohm coax is
never measured at the meter. So we never really measure the reflected
power coming right out of the PA, even if we attach the meter directly
to it's output.

After the first two replies on a question it is usually beter to give up.
Right or wrong one just can not win.

I have not seen a whole lot of equations on SWR but the few I have seen
never mention the source at all.

How about a 50 Ohm resistor, which is always 50 Ohms (impedance
doesn't change), fed with 20 ohms? Or 75?

Cecil is correct in saying that the SWR meter would then have to
be designed for 20 or 75 ohms, but that is beside the point.

SWR doesn't have to be strictly 50 ohms, and will involve TWO
impedances. If your source doesn't match your reference impedance
(normalized center of Smith Chart), then you won't be measuring the
reflected power coming right off the source.

And because most PA are not 50 ohms output, and most SWR meters
are 50 Ohms, there is problem.

> As Roy says, the equations relating any one of these parameters to any
> other are all well known. NONE of them ever involves source impedance.

> has no relevance whatever to your earlier statements about source
> impedance.

it's very relevant if you consider the port on a network analyzer
to be 50 ohms or not... It should be, but your PA may be quite far
off.

Source record: 110673

What's the source for this data? How long is the line in wavelengths? At
50 Hz one wavelength is 3,720 miles. I would expect that the test line
was more like wire than transmission line!

At 100 kHz, one wavelength is 1.86 miles. I suspect that the test line
was still a non significant section of a wavelength therefore acting
more like a wire than a transmission line.

At 1 MHz and higher the data looks like a transmission line. The data
seems to indicates a transmission line that is about 1.4 to 1.5 meters
long!!!

I hope you are trying to pull our legs with this "DATA"

Of course. We have no phase information. Only the magnitude of
the voltage reflection coefficient.

> This also brings up another point: do YOU define S11 to be the same
> as reflection coefficient?
>
> Cheers,
> Tom

I define the S11 as the complex impedance, which never changes,
but S11 can also refer to the magnitude of the reflection coefficient
at a particular phase, AT A PARTICULAR NORMALIZED REFERENCE IMPEDANCE.
If you define the reflection coefficient as having phase
information, then yes, they are the same, but only at a particular
reference impedance.

Change the reference impedance, and you will have a new reflection
coefficient, but the complex impedance will still be measured to be
the same.

You can do this is Motorola's Impedance Matching Program (MIMP).

What this all comes down to is that your 50 Ohm SWR meters only
measure reflected powers after it, not before, so any mismatch from PA
to reference impedance (50 ohm coax from PA to meter) is not measured.

Exactly! And (in a linear, time-invariant system at steady-state,
with enough forward power to be interesting,) that ratio does not
depend on where the forward power comes from; it's determined by the
load attached to the line and the line itself. (I trust we ARE
talking about a situation with only one source, feeding only one end
of the line...)

By improve, i mean increase the incident power. I think this is
possible, and i've actually measured it, if you read my original post.

If you can improve the incident power (tuning) of a PA with
varying the coax length, you might be able to adjust the SWR too, in
certain cases... though in my case, the SWR stayed about the same.

I never thought about coax having a low frequency effect, but makes sense.
Twisted pair telephone wire is considered to be 600 - 900 Ohms with a large
capacitive component at voice frequencies, by 25KHz it is about 135, and at
T1/E1 frequencies, which are over 1 MHz, about 100 Ohms.

In the case of a paint can being used for the housing for a dummy load
the outer surface of the can needs to be able to radiate as much power
as possible. A Teflon liner between the oil and inner surface of the
metal can is a thermal insulator and will degrade the ability of the
can and the dummy load to transfer the BTUs in the oil to the air
surrounding the can.

Simply degrease the can thoroughly and resolder the seams. Still won't
get rid of all the oil forever because the relief valves burp and/or
leak here and there.

> If viscosity is your main concern then additional

> (ARRL shows a method of achieving this)

I once wound a double-layer full length coil of 1/4" copper tubing
which was immersed in the mineral oil and soldered into the lid of a
Cantenna. I ran faucet water thru the coil. The dummy load ran quite
cool under all conditions when we were key-down smoke testing 2kW
output HF amps for an hour at a crack.

Dummy loads are simply places where one can dump RF power without cluttering up the bands. And I certainly wouldn't get involved with winding any inductors when non-inductive 50 Ohm deposited-film resistors are freely available.

> As a point of interest, have you considered what creates
> the first point of failure,

No, I've never had a dummy load fail.

> and why transformers housings
> are built so mechanically strong ?

Because they're the stuctural supports and housings for particulaly heavy AC power machinery often located outdoors and subject to all sorts of physical abuse. Plus the shells need to be of heavy enough plate to reliably facilitate leakproof welds. I fail to understand what this topic has to do with ham radio dummy load mechanicals.

> Can you tell me at what
> time the 'flash point ' comes into play when considering

No, but if the flash point ever becomes a concern I'll look up the temp and take it from there.

Those same resistors were specified at ï¿½20% for ordinary production
runs. Time has nothing to do with any implication of value drift when
the initial value far exceeds the worst drift in the worst of
circumstances.

Hi Brian,

As an aside to Art's observation, the world's best resistors (for
drift and accuracy) are stored in oil. They are roughly the size of a
coke can (actually thinner and taller, maybe the "new" coke can size)
and a Watt of dissipation would stress them (through the tension of
the wire element by thermal expansion).

The best oil I would search for (if it really mattered all that much,
it doesn't) would be Dow-Corning 200CP Silicone Fluid. This is what
is used in HP's Caloric Power meter. Problem there, and shared with
many of these exotic suggestions, is the minimum one barrel order. I
think someone earlier suggested begging which seems the best bet still

going.

Attach a physical ground and see what happens. You may somehow have
lost the capacitive coupling.

Don't tell my wife that. She's been thinking all along that the food she's been putting in the Teflon lined frying pan has actually been cooking!

Seriously, what you've got is a series of "thermal resistances" in series. This is a legitimate if simplified way of evaluating temperature drop, and is widely used in determining chip temperature of transistors and ICs. From the resistor, you've got the thermal resistance of the oil, in series with the thermal resistance of the Teflon, then the metal can, then finally the resistance of the can-to-air transfer, or "connection". The temperature difference between the resistor and the air is calculated like the voltage in a circuit, where the circuit's "current" is the amount of power being transferred. That is, DT = THETA * P, where DT is the temperature differential, P the power, and THETA all the thermal resistances in series. In electronics, DT is usually in degrees C, P in watts, and THETA in degrees C per watt.

While the thermal resistance of the Teflon layer is undoubtedly several orders of magnitude greater than the thermal resistance of the can, I'd be willing to bet that it's much less than the can-to-air thermal resistance, and probably (because of its very small thickness) even much less than the resistor-to-Teflon thermal resistance through the oil (unless, perhaps, the oil is very rapidly stirred). So, in the big picture, the Teflon layer doesn't make any difference.

For Dr. Slick: Knowing the forward and reflected powers, one can use the
following equation to obtain SWR. 'Sqrt' means "square root of".

SWR = [Sqrt(Pfwd)+Sqrt(Pref)]/[Sqrt(Pfwd)-Sqrt(Pref)]

I disagree that it's not of any practical use. The MFJ antenna analyzer uses essentially this method, and on every occasion where I've used it (mostly on RG-58 cable, occasionally on RG-213), it agrees within a tenth of a dB or so with measurements made with a Bird wattmeter. Agreed that the Bird isn't terribly accurate, but it's not too bad for comparative readings where the differences aren't great.

Assuming that the measurement is made with an SWR meter, I agree that the result won't be accurate if the line impedance is different from the SWR meter's. However, for the normal variations one sees in "50 ohm" cable, the results are accurate enough to be quite useful. The method certainly shouldn't be used for lines whose nominal characteristic impedance isn't the same as the meter's. I apologize for not pointing this out, and thank Reg for doing so.

Contrary to (1) below, no slotted line or voltmeter is necessary to use this equation.

I do agree that this wouldn't be a good method to measure very small amounts of loss. But for the original purpose of deciding whether old cable is usable, it should be fine. If the loss is that small, there's no reason not to use the line.

There are many occasions where a casual measurement is better than no measurement at all -- always with the caveat that you realize the limitations of the measurement's accuracy and don't try to draw conclusions from it that aren't justified. This is certainly a method that gives results which, under a number of circumstances, is quite useful.

If the forward power out of a PA is 100 watts and the reflected power
into the PA is 50 watts, the PA is generating 50 watts, *by definition*.

Given that definition, the implication is clear. All PA's, by definition,
must re-reflect 100% of the incident reflected energy. Thus, everything
you are worried about has already been defined out of existence. :-)

When someone defined the generated power as the forward power minus the
reflected power, the entire problem was defined out of existence. :-)

Dr. Slick wrote:
> And because most PA are not 50 ohms output, and most SWR meters
> are 50 Ohms, there is problem.

The problem is solved by the 50 ohm coax. No matter what power the generator is generating, the ratio of Vfwd/Ifwd is 50 ohms. No matter what reflected power is incident upon the generator, the ratio of Vref/Iref is 50 ohms. The PA is forced to accept those conditions. The load is in control of the PA's load line. A generator putting out 100V at 2A can have an internal impedance of 5 ohms, 50 ohms, 500 ohms, or anything else.

By definition. I wonder who invented that definition? It seems pretty
obvious that not all PA's are Z0-matched so they will always re-reflect
100% of the incident reflected power. But that is exactly what that
definition implies.

Dear all, Here's a useful tip -

The loss along any sort of HF transmission line, SWR or not, increases with line temperature according to just ONE HALF of the resistance-temperature coefficient of the conductors. Why ? It's something to do with skin effect.

RTC of copper is near enough 0.4 percent per degree C.

So loss along any line, in dB or nepers, increases by 0.2 percent per degree C.

Now you may not think this matters very much. But if you consider a seasonal change in temperature on the ocean bottom of only 2 degree C along a 2000-mile transatlantic cable which has an attenuation at 5 MHz of 1.6 dB per mile, total attenuation = 3,200 dB, then you will appreciate the responsibilty laid on the shoulders of the design engineers of the first oceanic telephone cable systems.

An uncertainty of 0.4 percent of 3,200 dB = 13 dB which is enough to wreck system operation. Omission of a submerged repeater allows signals to fall below noise level at the last repeater. Addition of one more repeater overloads the last repeater causing cross-modulation, cross-talk and noise. Bear in mind repeaters are both-direction amplifiers and the lowest speech channels are at 60 KHz where overall attenuation over the same distance is only about 350 dB.

Repeater power is fedover the the inner cable conductor from constant current sources at both ends, maximum voltage = 10 KV. +ve from one end, -ve from the other. During magnetic storms and other disturbances the potential difference between ground electrodes in N.America and W.Europe can rise to several thousand volts. Although the last time I measured it on an AVO-8 it was only 1.3 volts. I did, of course, make use of the safety grounding stick before using the crocodile clips on the ends of the meter leads. Depended on the tides and the flow of the Gulf Stream across the Earth's magnetic line of force.

It always struck me as being highly incongruous, even absurd, that in normal operation, cables of the highest possible quality materials, manufactured by automatically controlled, specially-designed precision machinery, laid at great expense by an 8000-ton, specially-design ship over thousands of miles, should end up by being terminated with a foot or so of soldered, screwed-up, cotton-covered 22-gauge wire rescued from the terminal-station scrap bin. This is true. I have seen both ends with my own eyes. On one occasion I even did the soldering after completing overall tests! But I was careful to use a fairly straight length of wire with sufficient sag to eliminate any

possible tension beyond that due to its own weight.

Dear readers, believe me, there's no time to worry about SWR when loss in revenue amounts to $100,000 per hour + repair-ship expenses every time a flatfish trawler scoops up a cable in its net, cuts it free with an axe, and the skipper sneaks away at top speed without telling anybody in case he has to pay for the damage.

Coax cable Zo = 43 ohms. Diameter over polyethylene = 1 inch. Inner conductor = longitudinal overlapping crimped copper tape, laid over the cable's principal strength-member of a number of high-tensile steel wires, overall inner diameter about 1/3 inch. Outer conductor = 6, touching, longitudinal aluminium tapes with a small spiral lay. Sheath = 0.1-inch thick extrusion of black polyethylene if I remember correctly. For shallow water and continental shelves there was a number of protective heavy iron wires laid on a bed of tarred hessian as had been used for 100 years on the first of the Atlantic telegraph cables.

I sometimes think of (the later) Lord Kelvin who followed his calculations with the recommendation to investors "Go ahead, make and lay the bloody stuff". But it was Heaviside, a generation later, a genius who died of neglect, who eventually described how the "bloody stuff" and radio propagation really worked.

Folks, just a little light-hearted digression, a respite from so-called SWR meters. Please continue with your discussion. ;o)

I have had a model 200 on the left rear of my Expedition for about a year now. It is very tuff! There are lots of low trees on the approach to my house and it hits them all. My wife tried to destroy it by hanging the whip in the basketball goal.. It bent the Steel channel iron mount and turned over the basketball goal which rode down the Tarheel.. It dinged the paint in one spot.. That was the only damage to the antenna and the paint has not chipped from where it was damaged.. Performance wise, and in short, It works GREAT!

I used The optional mount and it is also very durable... Works well with the Automatic Screwdriver Antenna Controller. (dosn't like to tune 40m when it's raining though).

Robert who makes the tarheel is a really nice fellow. He answered all kinds of questions for me when I was making my purchase decision.

My model 200 tunes 10-80 and also works very well on 6 meters. I don't even have to take the whip off. I don't know if yours will do this but I just tune mine to 20 meters and it is just right for 6m.

I have recommended this antenna to others before and I encourage you to try it. I don't think you will be disappointed

Depending upon it's length and how it is terminated, telephone twisted pair
is
approximately 5 - 10K Ohms and highly capacitive at the very low end near
100 - 200 Hz and only reaches 600 Ohms somewhere in the range of
1 - 2 KHz and then as you noted it continues downward to around 100 Ohms
at over 1MHz. In the usual lengths in which it is deployed by the telephone
companies,
i.e. [1500 Ohm design rules which "reach" to a maximum of 18,000 feet] it is
quite lossy usually having a DC resistance in the neighbourhood of 1500
Ohms.

For modern xDSL systems which span from a few hundred Hz up into the MHz,
the telephone twisted pair can fairly be considered a very lossy broad band
channel with
essentially no constant Zo. Zo varies all over the map! Cecil would have a
problem
calculating his "reflections" without a constant Zo, heh, heh... To
complicate things, such lines
often contains bridged taps, which are open circuit stubs hanging off the
line for "sparing"
purposes, and these stubs causes 1/4 wave "suck out" notches in the broad
band
transmission bandwidth.

Full duplex echo cancelled data transmission by xDSL techniques over such
channels
is problematic to say the least, but occurs in millions of instances daily.
In some xDSLs
the transmitters are operating simultaneously in the same bandwidth from
both ends while
the receivers on both ends have to operate in the presence of those local
transmitters over

18,000 foot distances with high attenuation and lots of cross-talk without errors.

All of this is accomplished with dedicated DSP processors.

Can anyone tell me what they think about the Steppir Antenna's? I have a High Sierra and like the antenna alot but hate the manual tuning.

Thanks in Advance Carl

NO - and this is the central point.

When Roy and I are saying:
>>NONE of them ever involves source impedance.
- that is exactly what we mean.

We didn't mean there is a hidden assumption about what the source impedance is - we meant what we said: it isn't there at all, in any of the equations we're talking about.

Look them up; and then go deeper and look at how they are derived. They involve only the load impedance and Z0. That's "only", as in "no hidden additives."

>electrically grounded to the boom?

Tonna's production over the last several years uses insulated plastic clips on top of the boom. These came in at about the same time as the sleeve "balun" for the driven element.

If you're offered an old one that uses elements through the boom with metal clips, you should probably just say no. At its present age the boom-element contacts will be corroded and unreliable.

With all old Tonnas, there's also a question about corrosion of the riveted joint between the driven element and the hairpin loop, inside the insulator where you can't get to clean it. I've used Tonnas for many years, but on new driven elements I now apply hot-melt glue around the locations where water could get in.

Yes - the very next sentence that I wrote, and you deleted:

>>SWR on a transmission line connecting the source and load impedance
>>is a totally separate quantity, determined only by the load impedance
>>and Z0.

The subject is why SWR meters might read differently with different
lengths of coax. Your statements about mismatch uncertainty are true,
but not relevant.

The word "slab" was probably a poor choice. I was mainly referring to the width, not depth, of the concrete. The concrete will pretty much fill the entire hole below the ground surface.

To make it freestanding, one would have to use some fairly thick steel pipe (both wall thickness and pipe diameter), especially for longer lengths. And pipe that heavy would almost require a crane to move it around. Because of that, steel pipe might be fine for shorter masts (or guyed taller masts using thinner pipe), but wouldn't really be feasible for a taller freestanding structure (unless one owned a crane, but then the crane itself could just be used to support the antennas).

Thanks Mark for your reply.
It was on the MoonRaker web site http://www.moonrakerukltd.com they called it a phasing line on there G5RV.
All noted on the external ATU. I was hoping to rely on the one in the FT1000MP Field. Looks as if I will have to sort some thing out with a external ATU this way.

I've found myself in the position of having to chase down small quantities of exotic lubes normally sold only in barrel type quantities by the producers. There are "job lot" suppliers out there which repackage the stuff in smaller quantities. But boy, tracking them down was quite an exercise.

I spent a day and a half on the phone calling around trying to buy a lousy two pounds of a specific DuPont Teflon-bearing grease. The worn-out DuPont tech rep finally wrote an order for a two pound sample but I had to drive 50 miles to the Dupey warehouse to pick it up.

I imagine it's much easier to simply run a web search today.

Peter,

I once worked on stuff that operated on leased 4 wire lines in the frequency range of a few KHz to about 200 Khz. We were told by Telco systems engineers to design for 135 Ohms. There were restrictions on what cable was usable. 19 ga was OK, 26 was definately not. Loading coils had to be removed. I think it was called a "G" something conditioned line.

There is an FCC approved model for a telephone line input impedance at voice frequencies. I can't remember the details, but it was something like two resistors in series with a sum of around 1000 Ohms; the larger resistor being shunted with a fair sized capacitor. You need this model to design, for instance, a hybrid for a modem.

When the line is very short relative to a wavelength you could treat it as something other than a transmission line. For instance, I once used a 1 inch length of RG 58 as a neutralizing capacitor for an HF traansmitter.

Yup. There isn't a steady-state thermal circuit out there which can't
be modeled on the bench with a pile of resistors. Gets hairy when
fluid dyanmics gets into the mix, laminar vs. turbulent flow, etc.
Ditto the electrical network simulation of mechanical vibrations. A
lot of grad school theses were written in the general topic area back
in analog computer days. Mother Nature could care less about the lines
between engineering disciplines.

> While the thermal resistance of the Teflon layer is undoubtedly several

I've done it both ways depending on a lot of variables. I noramally do
use threaded pipe reducers. As long as they're either steel or wrought
iron that is. The cheap hardware store cast grey iron reducers are
non-no's. I retap the reducers to get more thread engagement length.
It's been demonstrated that Schedule 40 pipe will fail in bending
before decent reducers fail. But in situations where the loads get
dicey and/or parts of the mast are tubing vs. pipe I use at least six
inch overlaps and have the joints welded.

Dwight,

My first tower consisted of 3 sections of Rohn HBX. This gave me 24 feet. To the top of this I added a 10 foot piece of 2 inch OD Al pipe. This was fastened to the tower with angle iron and U bolts at the top plate and the rotor shelf. Somebody gave it to me. It actually started life as a Hygain vertical. The middle of the second section was fastened to the end of the garage with TV house brackets. The ground mount consisted of three pieces of pipe driven into the ground, with 1 bag of concrete to add some strength.

BTW, have you considered a roof tower? Even a garage roof would give you at least 12 free feet.

Correction... First, thanks to Reg for his posting on the same
general topic. He pointed out that the RF resistances changes as the
square root of the DC resistance, and though I know that perfectly
well, had not put that into the above statements. With that
correction, I believe the result will be more like a change of 8% in
RF resistance, a loss change from 3.00dB to 3.26dB, and a change from
about 1.40 to 1.37 SWR. The point is the same; it would be observable
on a good SWR meter, though not distinguishable from other effects on
a typical cheap one.

Cheers,
Tom

Somewhere in all this mess, I believe RC posted that the OP's
originally posted observations supported his claim (that source
impedance affects line SWR), but yet when I go back and read the OP's
observations, they are that the POWER delivered to the load changes
significantly with line length and the measured line SWR DOES NOT
change noticably.

It seems to me that the OP's observations directly support that the
line SWR does not change with changes in source impedance: if the
transmitter output impedance is not equal to the line impedance, the
additional line can be though of as lumped with the transmitter and
where it connects to the original length would be the point where the
source impedance would be measured...and it would have changed
significantly with added line, while the SWR did not.

Cheers,
Tom

That's nonsense. If you want a properly-designed pipe mast you do it
by the numbers, not with amateur "eyeball structural engineering"
and/or broad-brush statements like "have to use some fairly thick
steel pipe . . ". You won't know a thing about any pipe sizes until
and unless you run the numbers. A 40 foot pipe mast analysis is as
simple as it gets in the field of applied mechanics, any sophomore
student in any engineering discipline including the EEs who brought
you your HT can handle the job. A pipe mast is just a classic
cantilever beam.

> And pipe that heavy would almost require a crane to move it around. Because
> of that, steel pipe might be fine for shorter masts (or guyed taller masts

> freestanding structure (unless one owned a crane, but then the crane itself
> could just be used to support the antennas).

You gather up five buddies. You hang a pulley near the house bracket.
Run a rope from the ground, thru the pulley then down to the midpoint
of the mast. There's your "crane". Three guys walk the mast up and two
pull on the rope and up she goes.

Hi,

Tahreel attends most of the NC hamfests and has their product on the table along

with those from other companies. It is what is inside that counts, outside can look
pretty and all but if there is junk parts inside it will not last.

Tarheel antenna last because they have quality parts and construction.

When I get my general (soon) time to buy a tarheel antenna !

May I suggest that you also invoke the laws of partial pressures?
As for those that are using motor oils and transmission fluids for
years
perhaps they should be reported for having weapons of mass destruction
(WMD) !
I am sure the 'authorities' will arrange for pick up for disposal in
Irak
so they can be readily 'found' and the exhausted searchers can finally
come home. We just had a transformer blow up in the County court
house which created multi $ damage to the superstructure .
Perhaps I should suggest that they look for a homemade dummy load gone
bad
and blame it on a CB er.

I bought a 30 foot tower from my local TV shop a few years back for $35.00 a 10 section. The company that makes it is American Tower I think they are in FL but a call to my local TV shop and he still sells the stuff only the price is now $41.00 a 10 foot section :-) It's free standing to 30 feet with a 3 foot X 3 foot X 3 foot base, or you can do what I did and stick 3 feet of the 30 foot tower in a 3' X 3' X 3' hole and fill it with quickcrete and run the garden hose on it for a few min :-) I used 2 U clamps to clamp it to the house in the middel of the 2nd section so my tower is good to 50 feet I'm told with a 6sq ft load

Hi Ian,

Look at the subject line above. Everything reported by me responds directly to it. I notice you have nothing relevant to add in that regard.

To this point NO ONE has responded to the data, nor to the authoritative citations. It would be more useful for you folks to point out error rather than simply arm-chair your way through this with denial. To this point NO ONE has offered any synopsis of my error in method. Such close examination appears to be confined to re-evaluations of the CFA which lack both, and thus make a more amusing target that does not test anyone's skill beyond debate. In the words of Ho Chi Minh: "Paper Tigers."

Also to this point, the only "critics" have been those with a voiced interest in not assigning a value to Source Z, but again demonstrating a more than ample capacity to arm-chair their way through byzantine explanations of what it is "not." Bench work seems to be anathema, however I do enjoy the zen-cartwheels being performed, thanks.

If I were to offer this with the infinite regress of Cecil's logic, hide my data, and embellish my method, you would all be compounding this thread to 600 entries. I don't play that game, sorry to disappoint you fellows, but I don't write to entertain (even if I can do it better than you without really trying - sometimes, like now, opportunity begs). The repetition of data, like denial, is not debate, so I am satisfied to post real bench work once, and pull paper tails until that goes stale.

I am particularly amused by protestations that examination of data is not worth anyone's time, but offering editorialization is. :-)
Clearly most of you should take more pleasure in your amusing recreations.

You guys worry this out of all proportion, you act like this is especially important and it certainly seems to set your teeth on edge. As many would point out, this is only a hobby; it's not like your job

is on the line, or that you have to meet a customer's expectation. :-)

i've owned a 3 element for about 18
months now. i'm quite pleased with
it's performance and the level of support
i receive from john & company. i met
them at hamcom in arlington, tx several
months back and they are a pleasure to
talk to face to face. i especially like the
180 degree flip function.

pros: good f/b, gain, side rejection, fairly
light weight, easy assembly. essentially a
monobander from 13.8 mhz to 54 mhz.

cons: a bit on the expensive side, you really
need to keep varments away from the control
cable.

final recommendation: buy one, you'll love it

Hi Tom,

Thanks for actually looking. You are indeed correct in your statement
about the "small" variation of SWR:
>SWR DOES NOT change noticably.
This, too, is consistent with the data I have offered. Casual
benchwork is as likely to reveal that as not. This is to say that no
real examination was originally performed, it was discovered by
accident (the portents of the variation of Power were more
distracting) and the readings were discarded as, perhaps, simple
statistical fluctuation. If through the sheer chance of opportunistic
luck in drawing different line lengths into the original posting,
those values may have been far more significant. If I had trimmed my
data to a very short interval, it would have matched his. The
variation follows a sine curve shape (if anyone had actually viewed
the data, this would be obvious) and you can take several readings
along the slope with alarm, or several along the crest to
indifference. This simply reveals that the original posting lacked

many essential details, but contained many confirmatory ones.

This does not change the fact that as a subset of my data, that it lacks supporting my results simply because it does not go to the breadth nor depth of my study. I in fact offered three significant quotes of his original observations made that are classic indicators of Mismatch Uncertainty. The simple point of that issue is that you cannot measure Power with any promise of accuracy when placed between two discontinuities. Unless you can describe all paths. This is a staple of simple wave interference. It necessarily follows that if you cannot determine Power due to this indeterminacy, you have no chance of determining SWR (you can certainly offer a reading and go on about life blithely unaware).

Simply put, I don't see anyone here willing to put their "faith" to the test; and I am the only one here with my skin in the game. I am far more likely to accept error through honest effort equal to mine that demonstrates it. But critics to this point have not only refused to step up to the bench, but they have also denied the argument through aggressively ignoring my methods and their results. I observe far more reading of my comments here, than with that one posting. As such, it is more than obvious that entertainment is the driving force for this criticism, not technical review.

Hi Brian,

That is exactly how I get all my exotic electronics parts, engineering samples. FREE. Need a 24 bit ADC? How about GHZ GBWP amps? Precision V-F-V converters? FREE.

Now, if I wanted to buy one they would tell me to take a hike.

As for your last comment about web searching. That is my current business. I build web robots and if anyone is interested, my current model that I call GrantBot will search through nearly 2000 pages of legislation funding of Grants offered and awarded by every department, agency, institute, consortium, office, bureau, center, program, group, division, administration, service, ... in the government.

This offer is free to individuals.

I have a generic robot that is workable, but which remains to gain recent work's improvements. However, it requires that you have some foreknowledge of potential links (it is a targeted web robot, not a free roaming one).

That too is free to individuals.

When I say individuals, that means those not using it as a tool of their paid work. If you are a sole proprietor, I still consider you an individual.

> Roy Lewallen, W7EL

That's a gray area, but let's say no. My thought was to find a part number, which he could then call any one of a dozen people up with, and ask if they have it, without giving a long explanation. In fact, maybe the first place he should go is the Belden web site, they may have a recommendation.

Actually, there may be a simpler solution. Put about a 4 - 6 inch length of heat shrink tubing over the jacket to build it up , and use a normal connector intended for 9913. There may be a problem with an RG8 type connector, in that the center conductor may not go in the pin hole.

Hi Tam,

Sounds more like the model for the K-1 relay, or a hybrid decoupling
network or balancing network description. Telephone is the land of
600 Ohm specifications (min. 550, max. 850) for many good reasons
related to their networks.

The passband for voice frequencies does not demonstrate any simple one
time constant roll-off characteristic. Ma Bell couldn't afford that
kind of waste.

THIS PLACE MIGHT BE A START if you got the surfin time for searching

http://www.fairradio.com/0mk-12.htm

12 foot Military Mast Kit. Comes with: three 47" long x 1 3/8"
fiberglass mast sections, one 8" top mast section which holds
two horizontal arial antennas and also has 16 feet of RG-58 coax
with a male BNC connection at the end, two 28" antenna elements
that thread to the top section, one guy ring with guy rope, three
9" stainless steel stakes, one 27" long mast base which mounts
directly into the ground, and O.D. green carrying bag with handle.
There is no indication of a model number on the assembly.
Excellent for field day or other portable antenna use.

12 lbs sh. #MK-12, $59.50 each; 2 for $99.50

Carl,

I've had a 3 element up since early July. Not a long time to comment on durability but I feel I can comment on performance.

I have it up about 50' on a tower. It replaced a Hygain TH3jr at the same height. So far I would say it's far superior to the Hygain. Hard to make comparisons since I took one down and replaced it with the SteppIR but I am able to work just about anything I can hear, even at QRP levels. We have a local net on 10M every week and there were always a few stations that were in the noise at my location. Now they are weak but Q5 copy.

Add to that the ability to tune everywhere from 13.5 to 54 and it's a great antenna. The signals on 17m are really exciting to hear. I have not tried the antenna on 6M as yet so I can't comment on that band.

Plusses:
1. Covers every band with gain and good swr.
2. The ability to switch 180 degrees or bi-directional in a few seconds.
3. Good gain, not bad F/B

Minuses:
1. Heavy, at around 45# it's no lightweight!
2. Moving parts. Have to wait until we go through a typical New England winter to really know how it stands up.
3. Expensive

I followed the newsgroups over the last year and from everything I would expect it to survive our winters. Its not cheap, but a Force 12 five band antenna is around $900 and a 10 element log is not much cheaper. I have it interfaced with my rig and computer and it tracks the rig frequency just fine. I have personally talked with the owners both at Boxboro and at Dayton. They are committed to great service and producing a good product. I would recommend them highly.

Feel free to drop me a note off line if you'd like more info.

See a few pictures at: http://webpages.charter.net/kk1w/photo.htm

That's one of those ...well, yah, kinda, sorta, almost, ...things.
Nature is going to take care of the genetic problems. Without
predators the genetic errors don't usually last long.

As for the weak, reducing the size of the heard leaves more food for
them to get stronger. So even with harvesting the strong the herd
will get stronger.

Yet there is no real, or at least perfect answer...even with predatory
animals. That solution also cycles.

For instance the Fox population cycles greatly from a few healthy
animals to a great many when food is plentiful. Then Mange sweeps
through the fox population decimating it (if you haven't seen it, it
looks something like a terminal case of very painful dandruff). The
heard will drop from over population to almost a rarity in a year or
two. Then the rabbit and varmint populations explode. OTOH "as I
recall" it takes the Fox population about eight to ten years to
recover and then the cycle begins again

Here in the metropolitan area we have a huge coyote population, or at
least far more than most people realize. They prey on deer,
particularly the weak in infirm. They are also good at keeping the
stray cat population down..

Cats who run loose all the time, don't last long around here...nor do
dogs. We also have Bobcats and even this far south in the more highly
populated areas the occasional black bear waders into town.

Hi Cecil,

How curious of you to have missed this pï¿½an to your style:
"The Cecilian Gambit, a variation on the Galilean Defense revisited"

Even more unfortunate, you are probably the only one who could simply confirm or refute my data through efforts at your own bench. This was posted July 20, some 25 days now and referenced perhaps a couple of days ago.

You might want to compare it to your puzzle that same couple of days ago when you compressed those then 22 days into 66 minutes. ;-)

I would counter your puzzle by moving the load outside of your hypothetical room (same load, same line, same drive, same room too). That can wait however.

Richard,

Thank you very much for posting that reference to John Juroshek's
article. It happens to cover a topic very near and dear to my heart,
and I called John and we had a nice chat about it. In addition, I
told him where I saw the reference, and asked him if he would say that
the SWR on a line, in steady state excitation, with a source at one
end and a load at the other, depended on the source's source
impedance. He said it of course does not, and cannot understand how
you would have interpreted it that way.

Should I check with any of the other authors?

Cheers,
Tom

Do they still sell sulfur candles...Solid sulfur and a binder in a what looks like s SKOAL tin, with a wick.

We'd put that on a tin pieplate in the attic, light it off, and go out in the yard for several hours

Everything in the attic would leave town or die

They were wrecking our bird feeders so we purchased one of the new
big ones that have a top of solid plastic that kinda looks like an
umbrella, but smooth.

The little buggers slid down the wire and then chewed through the top
where the attachment points fits.

Sooo...as I'm building a fiberglass airplane, I took a bunch of
"milled fibers" (just a lot of short fibers that almost make a springy
like powder. Kinda like a cotton ball but without the adhesion)

I mixed up a batch of mill fiber, cabosil (silicon dioxide) and Vinyl
Ester Resin (Dow Derakane) and filled the hole as well as the recess
on the inside of the top.

It must be the fibers as they absolutely will not bother that feeder
any more, although they do try to jump from the tree to the side of
it. That usually alerts my cat who is tall enough to stand on his
hind feet and put both front paws around the dead bolt on the door.
I've seen him pick birds out of the air at 6 feet and he's chased
every dog in the neighborhood home save one.

We had only had him for a few months when he took in after a squirrel.
The squirrel headed up the nearest tree...with "Streak" right behind
him. When the squirrel ran out of tree with the cat closing in the
squirrel jumped to safety ... except young cat in the heat of the
chase forgot he was 20 to 30 feet up and continued right after the
squirrel. Darn near landing on him too...Cat landed in the drive way
with a sound much akin to a ripe watermelon being dropped. He
immediately chased the squirrel to the next tree...but apparently he
had learned something...or was out of wind...He sat down and just
looked up. Yet I have seen him at more than twice his young size
still chase them up a tree, but I've never seen him jump out of the
top of one after a squirrel again.

>dozens of the little buggers. I had to seal up every opening in my
>house, and seal the corner molding on my vinyl siding. Brats would climb

Try throwing a hand full of mothballs around up there. That *usually*
drives them out.

Here it's not a problem because the Yellow Jackets will build nests
any where the tree rats could get in and the tree rats seem to avoid
the Yellow Jackets. Damn things were building a condo under the eves
at the front of my shop. The last I had noticed it was about the size
of a lemon and I dosed it with wasp and hornet killer. Then a friend
stopped by to look at the airplane project and antique radio station.
He wife remarked about he nest. I thought she was talking about the
lemon sized one...It had grown! Twas about a foot tall and nearly a
foot across.

I waited till after dark, turned on the outside spots which are only
about a foot from the nest and thoroughly hosed it with wasp and
hornet killer. Then knocked the remains down using a piece of
conduit. When I knocked it sown there were about 30 or 40 of them
still full of life in there. due to the lights they kept flying into
the siding which was covered with the bug killer so they didn't last
long.

Yesterday I took care of three more a the back of the house and two on
the front.

Last year I destroyed over 40 some nests in the yard. (in my tower
legs, under shingles, in pipes, drains, yard equipment, under siding
They built one nest under the siding near the south peak that actually
pulled the siding loose.) I think I used something like 27 cans of
Wasp and Hornet killer last year. The Local "Lowe's " store was
carrying the stuff in truckload lots. They said they had never sold
so much of the stuff and people were buying it by the case.

>up there and munch a hole into the attic. Then they got in through the

Try food (peanut butter?) at the bottom end and grease the inside.
If the attic is sealed up you can eventually go up and carry them
out....if you can stand the smell... OTOH if they get hungry enough
they will chew through most anything.

>would jump out when they got thirsty and hungry enough. We're at a
>standoff for the moment......

We also have a yearly batch of Raccoons that pretty much demolish our
bird feeders.

Hmm, I've never seen one, but it sounds interesting. It would be
noxious enough, but after the smoke dissapeared, should be safe enough.

After seeing the work I put into mine, the size of the parts, the
strength of the guys, the 17,000# guy anchors, my wife put her foot
down and said no more climbing the other guy's towers around town.
Course, she says I shouldn't be doing that kind of work for the young
guys at my age although I hear no complaints when I go up and work on
mine. http://www.rogerhalstead.com/tower.htm

We had one who was going to install a 100 foot 25G and mount the rotor
at the base. Although basically a sound idea in theory, he
unfortunately was using 1 1/2 chrome molly tube with 1/2 inch wall
and the rotor was supported between the tower legs about a foot above
the base.

I could barely manage to pick up one section of the tube and he had 6.
(I'm not all that big, but I do lift weights) Imagine the weight on
the rotor and tower base, let alone the momentum from the mass even

without the antennas.

We had a longggg talk.

He decided to mount the rotor on a separately supported steel plate
anchored to big concrete blocks on either side, but finally abandoned
the idea as getting too complex.

Hi Tom,

Feel free to do that. I cannot imagine I hold sway over that anyway.
Do you really need more proof, or is your question an honest enquiry
suggesting you accept the possibility that someone else may actually
stand with me?

You among the many have done more in less time. I can accept
negative, informed response. Can he explain my posting? That is the
more telling as it is MY statement, not your summary of it.

I am not looking to shift the goal posts during the game, the posting
contains the beginning and end of it. It stands alone, or it falls
because of its own errors, not those appended, removed, remodeled,
explained, or fancified through specious "debate." I find more
entertainment in bearding the complacency it meets.

I have seen my results dismissed. I hardly find it surprising, but
with repetition it seems those in chant mode are insecure with their
mantra. After all what purpose is there in saying it twice in a round
of three postings? (or 3 of 5, or 5 of 7....).

Hi Tom,

As an after thought, but not secondary in my mind (tho' certainly in the heat of response). You are welcome. I am glad that even the obscure references elicit a positive outcome regardless of how it suits my thesis. THIS is the point of my writing (the rest is simply the struggle of titanic ego).

>make any difference?

For a dipole it won't make a nickels worth of difference.
Plus if you look around you may find some of the aluminum hard line
for free. The half inch variety is a tad fragile though. Neither the
1/2 inch or 3/4 inch will make small radius bends well.

Contrary to popular belief, connectors are easy to make...use a brass
coupling (compression fitting) with the coax in one end and a PL-259
in the other for t he 1/2 inch variety.

I prefer the 3/4 inch stuff which is much more sturdy, but takes a bit
more work to make connectors. http://www.rogerhalstead.com/conn.htm
OTOH the loss is very low. For dipoles at a reasonable height the
match is *probably* better than the normal 52 ohm coax.

IF OTOH you want to use flexible coax and aren't running a lot of
power, or into the VHF bands, or long runs I'd not use the TV flexible
stuff with aluminum braid. The aluminum foil covered with tinned
copper braid works fine. The construction depends on who made the
stuff.

I'm no longer using the TV *stuff* in the system here, but it is
mainly due to the architecture of the installation. I use LMR-400 all
the way through and have close to 1500 feet of the stuff even though I
do use a remote switch for the low band wire antennas.

Hi OM,

Yes, among many variants.

Yes, it is not exactly admitted to, but neither does the author simply wash his hands of it.

It looks like a simple description of a short antenna fully recognizing losses borne by the shortcuts. If anything, it becomes an issue of craftsmanship and cost as there is very little left to consider.

You might find it easier to tune by sliding the Choke portion of it over a range of distance (I am thinking of the choke as a series of beads over the cable and thus mobile in some sense).

^ 12 lbs sh. #MK-12, $59.50 each; 2 for $99.50

I've used those before. I wouldn't use it for a home antenna because there isn't much to it but it would make a very nice temporary mast to take car-camping -- or perhaps just to keep in the car for civil emergencies. I'd buy one if I had a car.

I seem to recall that it was longer than 12 foot -- more than three sections anyway -- so I may be remembering another kit. Still, it will fit in the trunk very nicely.

A couple of questions about your data. What kind of coax and
connectors are used for the BVT? What kind of wattmeter was
used for the readings?

The load seems to be 50/3 = 16.67 ohms. I would like to see
the same data for a load of 50 ohms. Seems you are getting
the same resulting effect that I do (on purpose) when I vary
the length of my ladder-line while watching the 50 ohm SWR.
Your results may repeat every 1/2WL. What if you had gone
out to 20 feet instead of stopping at 15 feet?

One last thought. Did you consider common-mode current
possibilities?

This Earth, a tiny plot isolated in the vacuum of space, is already overpopulated with people.

Its resources are being seriously depleted, polluted - food, clean air, clean water, timber, oil.

But various facilities for selective culling have been available and employed with ever-increasing efficiency for 58 years. Genetic Engineering is being kept in reserve.

The question arises, who or what selects they who do the selecting ?

Now that is a good idea. We could just add eight or nine feet of pipe to the top of maybe two tower sections. That would give enough height, without breaking the bank. However, the base would have to be stronger. We live in an area where tropical storms are routine and hurricanes are not rare. I don't really expect it to stay up through a hurricane, but would like it to survive most tropical storm winds. A solid concrete base, as described elsewhere, would be better suited for the task.

> BTW, have you considered a roof tower? Even a

Yep, the roof is out. We're leasing the commercial building and they're very touchy about their relatively new roofing.

> We are discussing RF components. Not High Voltage spark coils and plugs.

No, we were discussing the conductivity of WD-40.

If you think WD-40 has a characteristic that affects "RF components"
and not "High Voltage", you aren't talking conductivity. And in
reference to your other message regarding a car radio, it is not
conductivity of WD-40 that is/was the problem.

WD-40 will change the dielectric constant of air-gap tuning
capacitors, as will anything other than air. Even the residual film
left behind can have an affect. Perhaps it could mess up inductors
as well, but I've not experienced that.

Source record: 110668

It won't be long before the ultimate fully automatic ATU is built into transceivers.

We've had AGC ever since the vari-mu screen-grid valve was invented 75 years back. This abolished the RF gain control but no doubt there is still a residue of moaners and groaners.

The present so-called SWR meter (a stupid instrument if ever there was one) can then be abolished from front panels and, indeed, exiled from radio shacks for evermore and a day. Good riddance!

To provide something to talk about, write on SWL cards and enter in log books, only the S-meter need be retained. This can be re-named "Received Signal Strength Meter" and calibrated in more meaningful terms such as decibels relative to 1 micro-watt.

It's obvious from its name, a signal strength meter always has been a power meter. Pre-21st Century Old Wives kindly note. ;o)

3225. Re: Coax Cable vs Freqency

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-15 00:45:58 UTC
From: k7itm@aol.com
Message-ID: <3200347.0308141645.66e189e8@posting.google.com>
Source record: 110570

An interesting number of significant figures, if it's to cover both
RG-58 and RG-11 types. I'd expect the RG-11 to converge a bit better
to 72-75 ohms, actually. I have a note I made some time ago in a
reference book that says, "Neglecting dielectric loss, if Zo = Ro+jXo,
Xo is approximately -0.180*Ro*A100*VF/f" where A100 is the attenuation
in dB/100 feet and f is the frequency in MHz. There. Now, at least
for RF, people should be able to generate their own tables.

Cheers,
Tom

Your vocabulary is very confusing here, Cecil. "Incident"
usually refers to the forward power, so when you say "incident
reflected" it's extremely confusing.

I believe the source of confusion is here:

PA----+----50 ohm line----+SWR meter+----50 ohm line----+50 ohm dummy
load
1 2 3

The "+" are connector points. You folks are saying that as you
change the PA (source) impedance, that the SWR you read will remain
the same, even if the incident power changes due to the change in
reflected power at point 1.

This i can agree with, as no matter how much incident power makes
it past the impedance discontinuity at point 1, the system after this
point will theoretically always reflect the same ratio of reflected
power to incident.
But, if you place an SWR meter of the same impedance as the output
of the PA at point 1, you will definitely see a change in SWR at point
1 as you change the PA impedance, as you are changing the reference
impedance (center of Smith re-normalized). This is what i thought you
meant when you said "change the source impedance", but you meant to
say "change the source, but keep the reference impedance the same".

Understood, assuming this is what you guys mean.

I was thinking about how you changed the impedance of your SWR
meter, and I doubt that simply changing the terminating resistors to
ground on both directional couplers is all you have to do.

I believe this because the SWR/power meter needs to be a Zo ohm
Thru, with a microstrip line of a certain dielectric thickness, and
particular width and spacing from the couplers. And you cannot change
these very easily.

Do you have a schematic for us to see?

The schematic would hardly differ greatly from one used for CB given the cognizant details are materials and physical placement issues (stray coupling and phase shift) that relate to wavelength dimensions. The only printed change would be component values that, again, were selected on the basis of frequency (and probably very little) or as suggested, the termination values (which are only material if you suck out a lot of power trying to measure it). The only reason to shift those same values, per Cecil's application, is to keep the same scale. Implications of "matching" bear only on how poorly the circuit operates (using a dud of a meter movement). In other words, a photograph with some indication of scale would be far more useful.

The device may be considered a bridge or a directional coupler, beyond that it is only a matter of coupling.

> for RF, people should be able to generate their own tables.
============================

Your formula is correct and indeed approximate. But it's not of much use unless you already know Ro, A100 and VF, all of which vary with frequency. It is approximate because it ignores a correction factor related to Sqr{(Wire Resistance) / (Wire inductive reactance)} which varies fast with frequency.

At sufficiently high frequencies, where Ro (whatever that value may be), A100 and VF have settled down, all that is necessary is to set Xo equal to zero and be done with it, just like book-cooking Mr Smith of chart fame did in 1938.

I produced the table to illustrate the peculiar unexpected effects which occur with the smaller, popular diameter coax cables as used by amateurs. I used the words "typical" and "type" in anticipation of remarks such as yours from already educated people. The table applies closely to RG-58. RG-11, as you pointed out, is 75-ohm nominal but its characteristics behave in a similar fashion.

It should be stated that twin, balanced lines of all impedances behave in the same way except that their HF characteristics extend down to considerably lower frequencies.

I had in mind there are now LF amateur bands and anyone who may wish to do transmission line calculations or use his SWR meter at low frequencies should be warned against measuring errors. It's obvious he wouldn't get much help from the present un-ending thread on that subject. ;o)

Use programs COAXPAIR and RJELINE3 for design and performance of transmission lines from power frequencies, audio frquencies, up to UHF using exact classical methods of analysis. Enter data in practical units and obtain results in the form you are accustomed to using. Everybody is familiar with the 1.5-inch diameter wires spaced 12 feet apart striding across the countryside. Have you ever wondered what a 500-mile length would sound like with a telephone at each end?

Reading a SWR at this point 1 (or 2 or 3), as specified above, would
simply be zero deflection confirming the remainder of the circuit has
no return.
>
> This i can agree with, as no matter how much incident power makes

It will reflect nothing, by specification of the circuit above.

> But, if you place an SWR meter of the SAME IMPEDANCE AS THE OUTPUT

But? What has departed will not turn around after the fact of
changing something as immaterial as this presumed meter Z (which is no
more than the minutia of the scale unless circuit gross dimensions
exceed wavelength considerations). If this were significant, the
meter circuit itself would be the point of discontinuity and thus
reflective, but this would be wholly unobserved because
1. The meter pick-up (as it were) follows the discontinuity
2. The power flowing from the meter encounters no other discontinuity
as specified by the circuit above.

Given 2., it follows that zero deflection will still resolve to zero
deflection irrespective of the meter's guts.

To force a reading would require reflection from the output of the
meter's bridge/coupler which simply casts the issue back to a lousy
meter design (but one with apparent high sensitivity - in other words,
it is sucking out a huge amount of power to do the same chore others
do better with less). One can certainly conspire to screw up by
simply ignoring circuit dimension and wavelength - or taking a chance
with selecting an anonymous instrument from the bottom of the drawer
(which is the same thing). Any reading other than zero deflection
from the circuit above would indeed indicate a system failure (the
instrument being part of the system). Take care that failure here is

measured by degree - any reading forces other tests and in and of it
self is not conclusive of anything.

Serious SWR measurement at high frequency is far more simply achieved
with greater precision, accuracy, and less impact on the system
employing the rather more creaky methods of a slotted line. With this
approach you can at least relate to the serious considerations of
characteristic Z and wavelength specific issues (and often answered
with simple plumbing components hand crafted once to last decades).
Calibration is as simple as replacing the ruler if it falls off (if
you first confirm that the connections are not reflective, but then we
return to the discussion above).

Once again, it is a chicken and egg problem. You need a better method
of SWR determination to validate a poorer one. There is no such thing
as self validating this particular instrument above HF. A poor Bird
Wattmeter is especially prone to reflective connections (notorious in
fact) and given those connections do this before the reading, many
users are quite satisfied in their state of ignorance. But again,
this hardly amounts to much, unless you wish to achieve an accurate
Power determination. Often the system reflections will eclipse those
of the connectors and still be perfectly useful in an industrial
setting. The user of the Bird in that community doesn't really care
about absolute Power, only relative Power with mediocre absolute
accuracy. Quite often they are simply tasked to confirm levels within
2 or 3dB; the instrument's slop of 1dB is often accounted for within
the methods of measuring those specified levels. The universality of
the Bird is due only to robustness.

Your circuit above is simply the first step in
selecting/calibrating/verifying an instrument. Throw a mismatch into
the game and lights will begin to flash.

Once again, you're confusing the SWR meter reading with the SWR on the line. When the line and SWR impedances are different, the two are *not* the same. When I speak of the SWR on the line, I mean the SWR on the line, not the meter reading.

Now look at the sentence you wrote. It's not very clear to me, but it would certainly make more sense if you replaced "the SWR" with "the SWR meter reading". Do *not* confuse the two.

I'm saying that the line SWR doesn't change when you change the source impedance. I didn't say anything about incident or reflected power anywhere. And I won't. Cecil probably said something about the incident and reflected power, but explanations in those terms are strictly up to him.

If you were to change the impedance of the left hand line (the one between the PA and meter), then the SWR on the left hand line would change, but the SWR on the right hand line wouldn't, and the SWR meter reading would remain the same. For that matter, you can do anything you want between the SWR meter and the PA -- add an impedance of any kind in series or parallel, change the left hand transmission line length and/or Z0, change the power, whatever you want, and it won't change either the meter's indicated SWR or the actual SWR on the right hand line. The rule is that whatever you change, it won't affect the SWR on any line that's "downstream" (toward the load) from the change you made.

> This i can agree with, as no matter how much incident power makes
> it past the impedance discontinuity at point 1, the system after this
> point will theoretically always reflect the same ratio of reflected
> power to incident.

Be really, really careful when you start talking about forward and reflected power. It can very easily lead you to wrong conclusions about what's going on. Just check the postings on this group for the past few months for evidence. All the phenomena you can observe and measure can be fully explained by looking at forward and reverse voltage and current waves, and it's a whole lot less hazardous.

One of the several problems with thinking in terms of forward and reflected power is that it's universally meant to refer to average power. So you've lost all time and phase information, making it impossible to clearly see how the traveling waves interact. If you must deal with "forward power" and "reverse power", do your thinking and calculations with voltage and current waves, then calculate the power when you're all done.

As I said before, the ratio of forward to reflected voltage or current is independent of the source impedance. That ratio, when measured at the load, is simply the reflection coefficient at that point.

> But, if you place an SWR meter of the same impedance as the output
> of the PA at point 1, you will definitely see a change in SWR at point
> 1 as you change the PA impedance, as you are changing the reference
> impedance (center of Smith re-normalized).

No, you won't see a change in the SWR at point 1 as you change the PA impedance. All the fiddling you do with your Smith chart just won't make it happen. Sorry.

The SWR, voltage, current, impedance, power, reflection coefficient, waves, or anything else don't change in response to your Smith chart exercises.

This is what i thought you
> meant when you said "change the source impedance", but you meant to
> say "change the source, but keep the reference impedance the same".

No. When I said change the source impedance, I meant change the source impedance. Surely we don't need a discussion about what "impedance" means? When you get out your grease pencil and change the reference value of your Smith chart, it doesn't magically change the waves on the line on your workbench.

>
> Understood, assuming this is what you guys mean.
>

It's time for me to leave this discussion. I've tried to make my statement as clearly and simply as I know how, but somehow people have decided that I really meant something else, or that there's this condition or that condition that cause exceptions to it, or that it all depends on what you scribble on your Smith chart with a grease pencil. It bears a striking resemblance to a political science (what an oxymoron!) course I took, in which we could make up any definition for anything, or any interpretation of anything anyone said or wrote (and

were encouraged to do so), and all were equally valid. I've spent too much time interacting with engineers and not nearly enough with politicians and philosophers to know how to deal well with this fuzziness. Anyone who really cares can look up the equations in a couple of minutes. I'm sure they're on the web, if you have an aversion to paper media.

Look up the equations, study them, understand them. If you don't believe them, make up your own equations. Then set up a couple of simple experiments to test them, and see which are right. That's how science and engineering are done.

Checked Belden first, before I posted. I formed the opinion that it
should be illegal for wire companies to sell RF coaxial cable for
which there are no connectors. ;-) As far as I could tell, Amp and
Amphenol didn't have anything, but Bowmar did. Bowmar seems a bit
hungrier, or else is just set up to run semi-specials. I found them
willing to talk with me about special BNC configurations that would
only sell around a thousand a year, for example, a few years back.

Yes, in fact that's what we have done for now. Two layers of a
particular heat shrink made a snug fit to the clamp nut on the
connectors we already had, and that let the connector assembly work
properly. Much better than the mess the 'lectricians made on the
first try.

Cheers,
Tom

Perhaps that are types and grades of motor oil out there that will work with certain types of resistors I dont think it very practical to research to find which are compatible. Perhaps the oil companies already know. You could make it a project to enquire with them and post the information on this news group.

It's certainly possible - and regularly done for short quarter-wave impedance transformers at VHF/UHF - but there are practical problems for making long runs: difficulty of obtaining center rod in long lengths, has to be built on-site, difficulty of splicing, standard connectors have to be adapted... and in the longer term: internal condensation and corrosion, difficulty of repairing...

Those are just a few problems that come to mind ,from experience with using shorter lengths outdoors in a damp climate (though you wouldn't think it right now in England).

Except for those special-purpose applications, it really isn't worth the trouble. It's easier to turn detective and find surplus sources of hardline such as 50-ohm Heliax (used at cellular sites world-wide) or the 75-ohm hardline used in the USA for cable TV.

:-)

It would make as much sense to fill the can with mud, add one
electrode, and feed it against the shell. Some may no doubt find
their life's mission in then determining what grade of oil (to replace
the water) would improve this option.

It would certainly offer more caloric mass than a resistor, is freely
available, and all would quite agree - conductive and lossy.

3246. Internal Resistance (?)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-15 07:45:32 UTC
From: "George, W5YR" <w5yr@att.net>
Message-ID: <wc0%a.101359$0v4.6995464@bgtnsc04-news.ops.worldnet.att.net>
Source record: 110589

About all that anyone needs to know about an amateur radio amplifier (transmitter) in order to use it properly is the output power level and the required load resistance. The latter is usually 50 ohms for a variety of reasons, most of which relate to convenience, availability of coax cables, test equipment impedance environment, etc. Beyond those values, there is nothing about the amplifier design which is used in designing and adjusting the remainder of the tuner, transmission line and antenna system. The power level is of importance only in telling us how much voltage and current is involved in various parts of the system.

The result is the ultimate in convenience. We need have no intimate knowledge of "what is in the black box" in order to use it properly. In fact, even if we had full knowledge of all the particulars of the design, we would still use only its required load resistance and power levels associated with it modulation waveforms, etc.

Our modern amateur transmitters and amplifiers even have a convenient meter on the front panel that tells us when we have met our obligation to provide a 50+j0 ohm load. It may be labeled "SWR" and calibrated in an unusual scale, but the important thing is that when it reads 0 or "1:1 SWR" that tells us that we have met the load resistance obligation - nothing more or less.

I think that a great deal of confusion over this whole issue comes from two sources:

1. vague efforts to apply the infamous "Maximum Power Transfer Theorem" from the early days in undergrad EE school; and

2. confusing an r-f transmitter output stage with the classical "signal generator" with a dissipative 50-ohm internal resistance.

Forget both of those irritants and concentrate on the required load for the transmitter, which the designer will provide and insist upon, and then adjust the antenna system to provide that load and all will be well.

At no point will anyone, including the r-f amp designer in all likelihood, know or even care what the so-called "internal resistance" of the amplifier happens to be. He demands only one thing: the specified load resistance. Given that, his design will deliver the required power, efficiency, heat load, harmonic content, distortion levels, etc. etc.

I know of no instance in the design of everything connected to the output port of the transmitter where there is need to know anything other than the required load resistance for the amplifier and the power levels (average, peak, etc.).

Why do folks make this so complicated, Ian?

Hi George,

And us folk need never worry about what is beneath the hood as long as
we don't need a mechanic. Sheesh, haven't you learned to turn the
knob until the meter is full scale? All you have to really remember
to push the button before you talk!

>The latter is usually 50 ohms for a variety of
>reasons, most of which relate to convenience, availability of coax cables,
>test equipment impedance environment, etc.

For which us same folk STILL don't give a fig. Are you some sort of
salesman? Who uses coax when telephone wire is free? You got stock
in this cable stuff? I got satellite and I don't need it.

> Beyond those values, there is
>nothing about the amplifier design which is used in designing and adjusting
>the remainder of the tuner, transmission line and antenna system.

What are you talking about designing? Is your charge card void? Do
the sales clerks ignore you? Have you consider stitching your own
semaphore flags for a hobby instead? At least no one would laugh as
much for all the arm waving.

>The power
>level is of importance only in telling us how much voltage and current is
>involved in various parts of the system.

None of us folk even think of voltage or current, this impotence is
not needed to make a contact. What's the point?

>
>The result is the ultimate in convenience.

Something that us folk take for granted and never give a thought to
because it is exactly that: convenient. Are you writing a magazine
article no one reads? I hope you include lots of pictures. I prefer
Reader's Dogma myself.

> We need have no intimate
>knowledge of "what is in the black box" in order to use it properly.

Us folk would ask "what is in the black box? What are YOU talking
about?" My boxes are brown like any from the liquor store. The only
black box I've seen was at the cemetery. I don't think I will worry
how to use THAT properly - thank you!

>In
>fact, even if we had full knowledge of all the particulars of the design, we

Who looks at that - are you one of those goggle-eyed professors that
try to 'splain the meaning of life? You missed that by a country mile
and still don't seem to have learned about what knobs are for. Twist
one and push buttons until someone talks back. Your black box
obviously has none of the modern conveniences, is it a telegraph?

I'm currently using this coax with a vertical and I'm very pleased with it.
I am building a 15 ele yagi for 2m and would like to use the Westflex but
I'm concerned that it might be a bit too stiff to use with a rotator mounted
antenna. Has anyone tried this ?

Thanks

Steve

Yes, to my grief. If it's bent sharply, the inner conductor is pushed sideways and the copper foil tears. Even if you use a very big loop, the bending still tends to be concentrated into two small areas at the ends of the loop.

It's better to get down below the rotator loop in a more flexible cable such as RG213, and then change to the low-loss Westflex for the longer part of the run.

> offer one?
>

VSWR and ISWR are usually referred to, as a matter
of convenience, simply as SWR. For example, see
W.C. Johnson "Transmission Lines and Networks"
1950 p.146.

VSWR can also be defined as:

VSWR = sqrt[(|Pfwd|+|Prefl|)/(|Pfwd|-|Prefl|)]

where the bars | | refer to "magnitude".

|Pfwd| and |Prefl| are what the Bird wattmeter
displays. If SWR (meaning VSWR or ISWR) are
needed, the above formula finds these. The Bird
meter uses the above fomula to find "VSWR".

There is also a seldom-used "Power Standing Wave
Ratio" defined as the square of the VSWR or ISWR.
If SWR refers to power rather than volts or amps
then PSWR is

PSWR = (|Pfwd|+|Prefl|)/(|Pfwd|-|Prefl)|

The problem is that finding the output impedance analytically is usually very difficult.

Measurement methods (usually questionable) have been proposed that "estimate" the output impedance. These tests can often be manipulated to get some desired result (for example 50 ohms).

The value of output impedance depends especially on signal level and also several other parameters, such as negative feedback.

Is the value of output impedance important? Sometimes in critical situations it can be. For example, a lowpass filter connected to the output of the PA may not be exactly correctly terminated at the input end. The error slightly affects the filter response, especially at the filter cutoff frequency. The passband ripple can also be affected. Most lowpass filter types can be designed for unequal values of generator and load impedances.

If the PA is broadband solid-state a sweep method can be used to optimize the filter design.

Usually these errors are unimportant, especially in typical Ham Radio.

"Forward power incident upon the load" or "Reflected power
incident upon the source" makes sense to me. Given the
definition of "incident", the reflected power has to
be incident upon something. Simply replace "incident upon"
with "arriving at".

Correction "real part of Poynting vector" noted.

The problem remains:

How is the *real* part of the antenna input
impedance, regardless of how it is fed and
regardless of what kind of antenna it is, get
"transformed" to the *real* 377 ohms of free space?

I believe (intuitively) that the reactive E and H
near-fields collaborate to create an impedance
transformation function, in much the same way as a
lumped-element reactive L and C network. In other
words, energy shuffling between inductive and
capacitive fields do the job and the E and H
fields modify to the real values of free space.
The details of this are murky, But I believe the
basic idea is correct.

Hello All,

I've tried to make a selection of the best info!

Look at my website:

http://www.qsl.net/pd0rkc

New amateur SOFTWARE.
COAX cable info (table).
Compare many ANTENNAS
(tonna/m2/diamond/flexa/cushcraft/cue-dee/hygain....more).
SATELLITE freq. keplerian elements, tracking software (the new NOVA, and
SATSCAPE).
KENWOOD microphone & reset info (and many more).
Datasheets electronics.
All you need is there to find!!!!!

If NOT let me know whats missing (my e-mail adres is on my website!).

Optics, by Hecht, has a section 2.10 - Cylindrical Waves.
There is an interesting statement in that section: "No solutions
in terms of arbitrary functions can now be found as there were
for both spherical and plane waves."

The net reactive impedance component on a standing-wave antenna
is the result of the superposition of forward and reflected waves
on the standing-wave antenna. Presumably, a traveling-wave antenna,
like a terminated Rhombic, doesn't have reactive impedance components.

So my question is: Since the voltage and current are always in phase
in a traveling-wave antenna, is the near field of a traveling-wave
antenna ever reactive?

Those of us who _do_ have to worry, in intimate detail, about
generator source impedances, are most thankful that we do NOT when we
put loads on our ham rigs. Thanks for a great posting that nicely
summarizes what a lot of us have been saying for a long time. Perhaps
Reg is right. Perhaps we SHOULD quit calling it an SWR meter and
instead call it a "Transmitter Load Indicator" (or perhaps transmitter
load error indicator).

When you plug an appliance into the mains, do you worry about what the
mains source impedance is, so long as it's low enough to maintain the
proper voltage? When you connect speakers to an amplifier, do you
worry about what the source impedance is, so long as it's low enough
to not materially affect damping? If not, why would you worry about
transmitter source impedance? Why would you not worry instead about
proving the proper load so the amplifier can do it's job right?

Cheers,
Tom

One mail at one newsgroup (is that spam?).
Some people see new adresses of other newsgroups! (hey is that an idea for people whoe does not know?).

I see often people complain at other people who trie to do the best with their info.
Some people use that to get atention from other complainers, they prefer to read
the comments on that, what a waist of time, use your energy for hamradio news.

Maybe it's better to put your comments on a new newsgroup (news: alt.complain?????).

Some parameters like negative feedback are built into the design, but
others like signal level (drive), tuning and loading are variables,
adjustable at the discretion of the operator. The output impedance
wanders where it will.

All these factors combine to make "What is my PA's output impedance?"
one of those questions that is rarely worth asking, because it doesn't
have any useful general answer.

>Is the value of output impedance important? Sometimes in critical

> So my question is: Since the voltage and current are always in phase
> in a traveling-wave antenna, is the near field of a traveling-wave
> antenna ever reactive?
==========

Cec, you're leading yourself astray again. What's reactance to do with anything other feedpoint impedance?

Stand at a distance from a very long Beverage antenna. Focus your attention on a particular half-wave length of it.

The voltage at one end of the half-wave will whizz up and down at a frequency of x megahertz.

At the the other end of the half-wave length the voltage will whizz down and up at x megahertz, ie., in time-antiphase with it.

Therefore, from where you are standing, the half-wavelength of wire will behave and radiate exactly like a half-wave dipole. You have no means of knowing whether there are standing waves along the wire or not. And clearly it doesn't matter. To segregate antennas between standing-wave and non-standing-wave types can be misleading.

To continue with the Beverage. Adjacent 1/2-wavelengths of wire form a co-linear array are in antiphase with each other. Therefore there is no broadside radiation from a long Beverage which contains an even number number of halfwavelengths. There is a sharp null at an angle of 90 degrees from the wire and as overall length increases so does the number of lobes in the general direction of the wire.

This is just the opposite of a co-linear array, a standing-wave antenna, along which the successive half-wave dipoles are all in time-phase with each other.

But both types of antenna incorporate radiating 1/2-wave dipoles. And if the near-field of one type has a reactive near-field (whatever THAT means) then so must the other.

If there are no standing waves it does NOT mean the voltage along the whole length of line or antenna is whizzing up and down in simultaneous time-phase in which case there would indeed be a non-reactive near field. But neither could there be any length or time delay involved.

Don't confuse instantaneous RF volts over a cycle with the envelope which may remain constant or vary with time or distance.

Reg, G4FGQ.

I'm just a sole these days, not a sole proprietor. For now anyway. I freelance in the industrial machine design biz but ran out of work in March and decided to coast with my feet up on the handlebars for a few months and do some radio, etc. Which is much easier when yer finally positioned to plunder the Social Security fund like I am now. Thanks for the offer Richard but I'm unloading tools rather than acquiring new ones.

Hi Bill,

Transformation, as a term, seems to be problematic without any more care for the preferred term of transduction (ignoring the historical usage it clashes with). How words could have any bearing on the process itself is more a calmative to the user than a need for the group.

So, if we were to simply ignore ALL the terms, how many show up at the table to discuss the PROCESS (I hope that's the right word...)?

If we simply cast off the electrical aspect of it (seeing how difficult it is to conduct discussion for this topic in that vernacular), the correlative of the organ pipe would be useful. It too creates a standing wave at the drive point; and it employs a resonant structure wherein the wave stands. It conforms to the transmission line principles of termination in that a close or open at the end is meaningful, and harmonically related to wavelength in a media. If this seems an outrage (because the former kidnapping of terms is ignored) consider the following quote from Reference Data for Radio Engineers:
"...Maxwell's initial work on electrical networks
was based on the previous work of Lagrange
in dynamic systems."
This reference then tumbles into the discussion of "Acoustic and Mechanical Networks and their Electrical Analogs"

It can be seen that the structure imposes critical significance in the harmonic component, but is wholly inert without excitation. In other words, it is not the causative agent, nor is it the agent of transmission. The pressure excess would cause air flow with or without it. Of course, there is an efficiency problem in that lax attitude and that necessarily brings us back to structure and fields (pressure in this case).

What has this to do with near field and far field? For the organ pipe, what is the near field, what is the far field? Here, we get into issues as we formerly did by looking at dimension and wavelength. There are two classes of Acoustic Impedance that bear to this intimately.

Those two classes compute for a spherical wave front, and for a planar wave front:
"...the acoustic impedance for a spherical
wave has an equivalent electrical circuit
comprising a resistance shunted by an inductance.
In this form, it is obvious that a small spherical
source (r is small) cannot radiate efficiently since
the radiation resistance [formula] is shunted by a small
inductance [formula]."

The plane wave Acoustic Impedance formula does not exhibit this inductive shunt. The difference between the two cases is simply a matter of scale, and is as arbitrarily chosen as with the abandoned antenna. That is to say, the definition of antenna far field being expressed as residing 10 wavelengths away also finds the correlative in this difference of Acoustic Impedance.

What is this shunt? The compressibility of the medium which is the mechanical analog of storage.

What is the difference between the case of the organ pipe and the antenna? For the pipe, the medium is lossy (and employing a vacuum brings its own obvious issues for the organ) and we find the loss expressed in phonons (the heat of jostling material). For the antenna (especially in the void of a vacuum, a useful medium) we find no such issue and consequently no related phonons (loss to heat within the medium). Some would note this also encompasses the traditional demarcation between transducer and transformer.

Irrespective of the difference, both exhibit a region wherein the MEDIA supports the transition (and perhaps we should call these structures transitioners --- only kidding :-).

As I stated in the past, it is absurd to crop the picture such that the description demands that an antenna ends at the literal tips of its structure as if virtual clips connect it to the ï¿½ther.

How can I lead myself astray by asking a question? :-)

Forget reactance. The question remains: Can the E-field and H-field
be out of phase if the voltage and current are in phase?

>
> Your vocabulary is very confusing here, Cecil. "Incident"
> usually refers to the forward power, so when you say "incident
> reflected" it's extremely confusing.

The point was not to confuse. So allow me to re-word it.

Some say there is zero power reflected from a PA. For that to
be true, all PA's must exhibit an impedance of Z0, i.e. all PA's
must be Z0-matched. Doesn't that seem a little far-fetched?

Some say that 100% of the reflected power is re-reflected by
the PA. For that to be true, all PA's must exhibit an open,
short, or pure reactance to the reflected waves. Doesn't that
seem a little far-fetched?

The problem lies in the definition of "generated power" which
is forward power minus reflected power. A mental exercise will
illustrate.

XMTR---one second long feedline-----mismatched load

For the first two seconds, a directional wattmeter at the
XMTR reads 100W forward, zero watts reflected.

During steady-state, the directional wattmeter reads 100W
forward, 25 watts reflected.

If the XMTR is a 100W signal generator equipped with a circulator
and load resistor, we have no problem deciding that the signal
generator is generating a continuous 100W and dissipating whatever
reflected energy arrives.

If the XMTR is a ham transmitter, we say it generates 100W for
two seconds, and after that, it generates 75 watts, by definition.
This seems to me to be just a useful shortcut that avoids opening
Pandora's Box (in which the source is located). :-)

If a transmitter only generates (forward power minus reflected
power), it follows that the transmitter always re-reflects 100%
of the reflected power arriving at its terminals. Does that

sound reasonable?

Or, if reflected energy is never re-reflected from a PA, then
the PA must be dissipating the reflected power, which it previously
generated, just like a signal generator with circulator load does.
Does that sound reasonable?

Or, if there is a circulator load, the reflected waves contain
energy, but if there's not a circulator load, the reflected waves
don't contain any energy. Does that sound reasonable?

What sounds reasonable to me is that the reflected waves arriving
back at the source obey the rules of the wave reflection model
as described by Ramo and Whinnery. But since the impedance presented
to the reflected waves by the transmitter is usually unknown, we
are again up that proverbial creek without a paddle.

So, by all means, use the shortcuts, but recognize that they are
definitional shortcuts which may or may not represent reality.

Ya take the vertical antenna & mast load out with a thrust bearing
either in the top plate or somewhere close to the top, run some loosly
guided 2-3" EMT down the tower and . . . does a great job of knocking
down the torsional start/braking/wind spikes throughout the system AND
reduces the number of climbs. A second thrust brg just above the
rotator is even better. I dunno where they come from.

It's a simple matter to model a Beverage with EZNEC and observe the near field at any point in space you'd like. EZNEC reports phase angles of the E and H fields, so it won't take long for you to find out.

There was a long-running series of exchanges about amp output impedeance, conjugate matching, etc. in QEX a couple of years ago. If I recall correctly, it was focused on measurement methods to determine this characteristic.

The 'Rules of the Road' for Usenet hold that a post is not spam if
it has a BI (Breidbart Index) of less than 20. The BI is calculated by
taking the square root of the total number of groups an article is
posted to.

Full details on this measure may be found here.

http://www.stopspam.org/usenet/mmf/breidbart.html

From what I can see, Cor posted an identical message to six
groups. The square root of six is about 2.45, so his message cannot be
considered spam under Usenet guidelines.

Said guidelines are here.

http://www.faqs.org/faqs/usenet/posting-rules/part1/

If his posts bother you, well... most Usenet newsreaders do have a
filter or 'killfile' function. ;-)

I simply cannot differentiate what part of the forward wave has been
reflected back from the source Vs what part is actually generated
by the source. That's the crux of the problem.

"Forward Incident" a bit redundant in my opinion. "Incident"
usually refers to the power moving towards the load, away from the
generator.

And your previous quote was: "It seems pretty
obvious that not all PA's are Z0-matched so they will always
re-reflect
100% of the incident reflected power."

So here, you don't say where it is "incident" upon, of where it
is arriving at, athough I assume you mean simply the reflected power.

I'm just trying to make your vocabulary less confusing.

I wouldn't pay for it. I would rather have a built in AC power supply. Not many people go mobile with a $2000 radio that weighs 25 lb; if they are serious about emergency communications, they will have a motor generator set. With a built in supply, you can run the transistors at some decent voltage, like 48V, and get your other voltages, like 3.3V and neg5V off the same transformer. You can buy a 300W PC power supply for $30, which means it costs less than $15 to make.

Since the power supply would be a 120/220 offline switcher, you could allow for 12V operation, if you insisted on it, by utilizing a tap on the transformer primary - probably add $5 to the cost.

I don't think that is true. The HP ap note, AN 95-1, refers to
"the voltage wave incident on port 1" and "the voltage wave
incident on port 2". Those two waves are moving in opposite
directions, one toward the load and one toward the source.

I mean in a 50 ohm referenced (normalized) Smith chart, a 60 ohm
transmission line will change the SWR of a non-50 ohm impedance (not
in the center), where as a perfect 50 ohm transmission line will
transform the impedance on a circle about the center of the chart,
which would be a constant VSWR circle.

I agree with you on this, but i stand by my statement that the
reflected power right at the output of the PA (connection 1), CAN
change as you change the output impedance of the PA. But, no one

really measures the S22, not mentioning the trouble it would take to
build an SWR meter for the impedance you get.

Absolutely incorrect. Time for you to review your Smith Chart
again.

If you re-normalize your Smith, your are changing the reference
impedance, and the SWR looking into the same complex impedance which
does not change.

This is typical of you, Roy, for you to back out of a discussion
when you don't want to admit that maybe someone else has a logical
point. I've agreed with you on many things (antennas as transducers

and such), but like many intelligent but close-minded people, you cannot accept someone elses points.

I guess you think other people can't teach you anything, eh?

NO ONE knows it all, even about a specific topic as impedance matching.

Hi Cecil,

>>> But since the impedance presented
>>>to the reflected waves by the transmitter is usually unknown
You have a forward part from the transmitter,
a reverse part from the reflection.

What more do you need unless you are discarding phase? If so, recover
it (if this is all about a SWR meter, then take out the diodes and use
a comparator).

For example, consider an EZNEC solution to an
antenna, say a 50 ohm dipole. The far-field 377
ohm solution provided by the program is precisely
the field that I am thinking about. How does
EZNEC, with its finite-element, method-of-moments
algorithm, transform a 50 ohm dipole input
resistance to 377 ohms in free space?

I don't want the equations, I want a word
description (preferably simple) of how EZNEC
performs this magic.

The far-field E and H fields are different from
the near-field E and H fields. What is going on?

We are talking about re-reflection FROM THE SOURCE!
The forward part and re-reflected part from the source
are coherent and traveling in the same direction so they
cannot be separated for measurement purposes. That's
why Bruene tried to determine the source impedance by
bouncing another separate signal off the source.

Hi Cecil,

That separation is unnecessary as it represents a sufficiently fixed
value for every moment beyond the first millisecond for usual
applications.

Let me explain why I leave these discussions.

I certainly don't know everything, and am constantly learning. But not from threads like this one. I can change the SWR on a transmission line by renormalizing my Smith chart? Is that a "logical point" I'm running away from?

The reason I post in the first place isn't to try and convince the party I'm directing my posting to. Nor is it an ego trip. What I hope to accomplish is to provide a counterpoint to what I see as incorrect information. This group is read by a very large number of "lurkers" who seldom or never post. I know this for a fact, because many of them introduce themselves to me at Dayton and other places I appear publicly. When someone posts misinformation on this group, I try to present what I consider to be correct.

There are people, some of whom post here, who won't be convinced regardless of the evidence. It's as much a total waste of time to argue with those people as it is to try and convince someone his religion is wrong. When I encounter a person like that, I'll post my point of view, present what evidence I can, then withdraw. I have much better things to do than continue flogging a dead horse. I feel that the lurkers, who are really the people I'm addressing, should be able to make up their minds on the basis of what's been presented.

There's more than ample evidence to back up what I've said that's easily available to anyone with a real interest in learning. Anyone who really cares and is willing to invest even a modicum of effort can search out

the information and reach a conclusion. You've chosen not to go to that effort(*), but rather interpret what I say in a way that suits your preconception. Sorry, I just won't waste more of my time trying to talk you out of it. If lurkers are convinced by your arguments and find them more compelling than the ones I've made, then so be it. I've done what I can. To continue posting over and over again the same thing isn't my choice of a way to use my time.

There are people who feel that the person who posts the last message "wins", and so anyone who withdraws has "lost". You can see the result of this philosophy in the threads that have run to literally hundreds of postings without ever resolving the issue. It's simply not a game I play.

Roy Lewallen, W7EL

(*) For example, have you ever looked up the equations for calculation of SWR? Noticed that there's no term for the source impedance? And no term for your Smith chart normalization factor?

Hi Bill,

The continuum of the structure presents a delay (by "moments" to use the vernacular of MOM) that combines with all "moments" of the previously existing and "near" separated field(s) to cause local free-space media fluctuations in Z. At a greater distance, such differences become trivial.

The local fields present a non-homogenous free-space media, some of which is transparent, some of which is reflective, much of it somewhere in between. The antenna distorts the medium it resides in presenting much the same effect as gravity distorting the space-time continuum. This is a leap of faith, certainly, but offers a visualization that may be familiar. In optics it would be something like dispersion where the structure is smaller than the wavelength exciting it.

So what part of the generated signal is actually generated and
what part is merely re-reflected energy?

EZNEC doesn't do the transformation you describe.

The following description is a very simplified version of how NEC works. I believe the whole NEC-2 manual is available on the web, for anyone who wants a deeper and surely more accurate explanation.

First, an impedance is calculated for each segment of each wire, and a mutual impedance for every segment relative to every other segment. This is done in a rather complex way by assuming that each segment has sine, cosine, and constant currents, calculating the field from each segment arriving at each other segment, and evaluating the current induced on the other segment by it. These impedances are put into a matrix, then the currents on each segment are found by solving Ohm's law in matrix form, where the E is provided by the specified sources. Once the currents are found, the impedance at each of the sources is known. The field from each segment is computed from the known current and assumed current distribution along the segment with an approximate integral equation that's solved numerically. The impedance of the medium (fixed at free space in NEC-2 but user selectable in NEC-4) is of course involved in this calculation, as it is for the mutual impedance calculation.

The fields are summed to obtain the overall field (both E and H) at any point the user specifies. Both are reported in a near field analysis output. In a far field calculation, the distance of the observation point to all segments is assumed to be the same, and only the E field is calculated.

An excellent and easy to follow description of the method of moments can be found in Kraus' _Antennas_, Second Ed. I assume it's in the third edition also, but it's not in the first. The NEC-2 manual recommends R.F. Harrington, _Field Computation by Moment Methods_ (McMillan, 1968) but I haven't seen this book.

I've tried to point out on this thread that although the feedpoint impedance is an impedance with the units of ohms, and the impedance of a plane wave in free space also has the units of ohms, they're not the same thing. Feedpoint impedance is the ratio of a current to a voltage. Wave impedance, or the intrinsic impedance of a medium, is the ratio of an E field to an H field -- it's also the square root of the ratio of the medium's permeability to its permittivity. An antenna converts currents and voltages to E and H fields, it doesn't just transform one impedance to another. Hence my insistence on calling an antenna a transducer rather than a transformer.

Any explanation of an antenna as a transformer will have to include parasitic array elements, which have zero feedpoint impedance, and array

elements that have negative feepoint resistances.

The answer to your last question is beyond my ability to answer. It's discussed in great detail in most electromagnetics and antenna texts.

What use would an inbuilt 120/220V supply be to someone in say, NYC or
Buffalo right now?

'Twas I who asked the question because I'm looking for an ATU so that I can
play about with antennas. I have mains PSUs for home use and I can draw
enough juice to run the FT-817 all day long from my mobility scooter and
wheelchair batteries without leaving myself stranded, but if the antenna
won't tune, nobody can hear me scream (thankfully!)

I can't see my S Meter [bar graph] without changing my specs and finding a
magnifying glass (damned miniaturisation!), but I stopped giving signal
reports when they started asking "What am I chucking you 5-4-3-2-1?" through
GB3RF back in the early 80's. If I can hear 'em, they're Q4 or Q5 (FM) or
R4 or 5 (SSB), except if they were calling CQ QRP when they'll get a full
report if requested. The only other exception is when they tell me they're
testing a new antenna or a new rig, then they get the full 'indicated'
report and I'll flick through the logbook for a previous report if there is
one. Of course this only applies to VHF, unless I was out with the club on
HF Field days

Good to meet you Reg. I think we've 'worked' this mode before when I was
with BTO, possibly in BTI support.

Hi Cecil,

Separation is unnecessary after the first millisecond. Impedance from
that time on is sufficiently fixed to measure. You can answer your
own question from the resultant, but it is of no particular interest
in the determination.

I would not go there on the audio . The speakers do need to match the design of the amp just as the load on a transmitter needs to match the design impedance. Most power output devices are designed to produce maximum power and /or minimum distortion into a specific load.

As Doc Squeegee has already explained, your posts are counted by a mathmatical rule called the Briedbart Index.

The Briedbart Index allows you 20 points in any consecutive 45 days. According to the DSRS archive which is the master archive used by all abuse departments, you "may" have already scored 12.63 points in the last 9 days. You appear to have no record before that date, so I assume *without any evidence pro or con* that you have changed your username or some other detail in your headers. Once your score reaches 20, then anybody with cancel rights is free to cancel your posts as spam and you may also be at risk of being added to the spam filter spools such as NoCeM, CancelMoose and Spam Hippo or your account with Chello.com may be closed, or both. It doesn't matter if your site is free or commercial. What matters is the way you post to usenet to advertise your website and the content of the message body.

People may have already lodged complaints against you for excessive crossposting. This is their right and I believe in this instance they have valid reason.

Crossposting fills other groups with unwanted replies and starts flame wars long after your advert has been removed. Your reply to Doc Squeegee has gone to 6 newsgroups. I trimmed to newsgroup line in my reply to cover only those groups which I regularly watch, and set a followup so that your reply would only come to this one group to reduce the risk of arguments starting. As per the convention, I posted a note in the first line of my reply as a top post.

For a copy of the rules in Dutch, Google "Rosalind Hengeveld". I'm pretty sure she put the rules on her website at xess4all.nl

I was talking about large100 - 200 W radios. They won't run long off a battery, and if the person is serious about emergency communications, they had better have an emergency generator. You can't even rotate your antenna without AC.

If I had a QRP rig, yes, I'd get a battery pack for it.

>and /or minimum distortion into a specific load.

Virtually all "HiFi" audio amplifiers are designed to have
"damping" factor of something significantly more than 10.
Damping factor is the ratio of the load impedance to the
amplifier's output impedance. You might even find a few (more
expensive units) that have ratios greater than 1000, which is to
say that the output impedance of the amp (designed to drive
speakers in the range of 4 to 16 Ohms), has an output impedance
of 4/1000 of an Ohm).

Just as with RF, the output impedance has little to do with the
power delivered to the load impedance. The amplifier can
generate a maximum voltage by design, and how much power is
actually delivered depends solely on the impedance of the load.
Hence the same amplifier can deliver twice the power to a 4 Ohm
speaker as it can to an 8 Ohm speaker, and that is twice what it
will deliver to a 16 Ohm speaker. And it also works just fine to
drive a 600 Ohm headset, with significantly less power.

> How can I lead myself astray by asking a question? :-)

You had led yourself astray long before you asked the question or you wouldn't have asked it. ;o)

> Forget reactance.

Good! I can't see why you dragged the reactance of fields in space into to the arena.

>The question remains: Can the E-field and H-field
> be out of phase if the voltage and current are in phase?

I answered your original question by saying that the near field due to a halfwavelength of wire along an antenna with standing waves (like a co-linear array of in-phase dipoles) was just the same as a halfwavelength along a wire in an antenna without any standing waves (like a Beverage). What applies to one must also apply to the other.

You have forgotten that fields exist in 3-dimensional space as well as in time. Movement (velocity) is also directly involved. Phase relationships between the various vectors depends on the direction (another vector) from which the observer (that's you) makes his observations.

Whereas, when you introduce volts and current in phase, you are referring only to a single point (in a straight length of wire) which has NO dimensions. It's just a location in space somewhere along a transmission line which is what an antenna wire actually is.

From occasional random sampling of the heated arguments presently taking place on this newsgroup it may be deduced that most of you baffle-gabbers don't have foggiest notions of what you are waffling about and there's no hope of you ever doing so unless you go back to school and the 12-times table and continue till you are familiar with Oliver Heaviside's mathematical description of electromagnetic radiation. There are only 3 simultaneous differential equations to contend with. As the ancient Iraqis and Greeks understood, all is a matter of Geometry in Motion. And THEY didn't have the benefit of Eznec.

I notice Roy has abandoned you to the wolves (CB-ers and M3-ers). His patience and hard labour have been exemplary.

Has that 50 million of you all got your electic lights fixed yet ? ;o)

Cecil excuses himself by saying it's the Devil who makes him do it. In my case it's only 3/4 of a bottle of Bulgarian red plonk.

Reg, G4FGQ, Hic!

Guys,

Try this out. You have an amplifier of unknown source impedance connected through a directional meter to a 1/4 wavelength line that is shorted at the far end. Without knowing about SWR, you know (because you are a ham radio operator) that the amp is driving an infinite impedance, and delivering 0 power. Now if you adjust the amp so the meter reads 100W in both directions, the amp is still delivering 0 power, and 100% of the reflected wave is rereflected. Where did the 100W come from? the amp delivered it during the first 1/2 cycle after it was turned on. It didn't "know" the line was shorted until the first reflection came back.

I heard a rumour they had an emergency in the States. The electricity failed. Errrrrm, you were saying?

My present mobility scooter has 2x 12V 60Ah Gell traction batteries. That's around a month with the 817 or 5 hrs continuous Tx with 100W. At 2% duty cycle, they would last longer than I can stay awake. For a real emergency, I've always found a cellphone to be more use than a radio

I was turning stacked and bayed 10 ele arrays by hand at VHF field events 20 some years ago. I've done the same with a couple of big dual band and tri band yagis at HF events. It's even easier with HF wire antennas. Just throw up two wires at right angles to each other and you have 360 degree coverage at the flick of an antenna changeover switch. There's still a lot to be said for the old ways of steam radio.

Beats me how the talk got around to power supplies and 200W rigs but that's the nature of amateur radio. I asked about an ATU which would suit my FT817 and a 100W rig which I haven't yet decided to buy because I've just seen the new Icom 7800. It's a moot point now anyway, I got fed up and ordered the ATU so let's talk antennas.

Do people really pay ?200 sterling (US$300) for a wire antenna? I've just seen the price of the Carolina Windom Short 80 Special

Unfortunately, that cannot be true. The maximum H-field amplitude at a current null cannot possibly be the same as the maximum H-field where a current null never exists.

How do you know that the amplifier is not "delivering" 100W of forward power
and dissipating 100W of reflected power (as it would with a circulator+load)?
How do you prove that the impedance looking back into the amp is zero, infinity,
or purely reactive? Doesn't it have everything to do with the arbitrary
definition of "delivered" which doesn't necessarily match reality?

Dear "Savage",

To use the american two-letter word - Hi!

There's insufficient info to deduce when and where we may have met in our previous lives. But I can confirm I am a long retired GPO engineer fortunate enough to escape just before Mrs T and Co. sold us off to the asset-stripping multi-national wolves.

Although I occasionally make (I hope humorously intended) criticisms of the contributions by frequenters of this newsgroup, there is no doubt about the group's high entertainment and, indeed, educational value, I have been a beneficiary and so become addicted to it.

I can't deny the benefit of a 20dB attenuator in seies with the aerial when assessing propagation conditions. But this is only because of imperfections which still remain in the AGC circuitry. They remain only because of the cost of improving receivers to the state when they can be considered to be received power level meters and calibrated in terms of dB relative to one microwatt.

Roy can then cease insisting that his own S-meter is the Western-world's standard of how many decibels are equivalent to one S-unit.

Reg, G4FGQ

Aha, I will give you special dispensation. You are allowed to bias the amp
for true class B, and measure the DC drain current. No way is the drain
current going to be different from the case of a plain open circuit. Power
(RF) can not be more than Power (DC)

> How do you prove that the impedance looking back into the amp is zero,

Use any RF impedance meter you want.

Doesn't it have everything to do with the arbitrary
> definition of "delivered" which doesn't necessarily match reality?

I think the only alternative in un nice; namely that there is no reflection
in steady state

I don't see how you can possibly assert that the fields are the same for
a standing-wave antenna and a traveling-wave antenna because they obviously
are not the same. A magnetic pickup at a current null on a standing-wave
antenna will read a low maximum value. A magnetic pickup at the same point
on a traveling-wave antenna will read a high maximum value.

You theorized uncertainty because of reflections from all directions.
You seem now to be "unconcerned" about that uncertainty.

There are an infinite number of possibilities between the rails of 100%
re-reflection and zero re-reflection. I suspect a PA obeys the rules of
the wave reflection model set forth in Ramo & Whinnery.

Hi Cecil,

In the first millisecond, yes. Do you have a question about it
following that point in time?

I don't recognise your callsign, but your name rings a small bell from somewhere in my rather colourful past. I was with BTO for a couple of years. I was the retro mod with a couple of {ahem} "adult content" groups, but I spent a lot of time sorting out BTO's spammer problems through their support groups.

Roy? The infamous Mr Lewallen? I enjoy reading his posts as I have yours

I had noticed the humour levels in these groups. I've been picking off the spammers rather than joining the chat, (got to earn my shekels) but I have

been reading and refreshing half forgotten theory from the good replies here. I didn't let my ticket lapse, but I lost a box containing most of my shack when I moved down to Cambs from Lancashire. The two rigs which survived the trip arrived here damaged, despite being properly packed and padded. Between the insurance companies and me developing the necessary qualifications to become a RAIBC member, I seem to have forgotten most of the important things through lack of use.

I did a lot of HF operating with G3BRS (Bury Radio Society), the late G4TBT and my pal, the lapsed G4ZTB, so when I heard about the impending changes, I bought an FT-817 and started reading.

I'm out of usenet and radio for about a month. I'm off to JA land in a few hours time and taking a detour to ZL on business on the way home, but I will return, hopefully with something hugely discounted which I can smuggle through customs cunningly disguised as a wheelchair battery charger.

I'm QTHR on the call sites/book/CD, but currently only active on 10/2/70cms due to lack of antennas. You can bet the Wx will be foul when I return to put something into the air, but that's life

See you further down the log. Been nice chatting with you (again?)

Bruce,

But did you look at the date of this material?

"Archive-name: usenet/spam-faq
Posting-Frequency: weekly
Last-modified: 1997/03/25"

Last-modified: 1997... It seems that this info is just over six years old, if I am reading the
article right. (Yes, I did read the article). Technologically speaking, this is ancient news,
worthy of needing to be 'updated' to today's standards.

You also need to consider *how many* different NGs a single person might subscribe to, and all
the additional messages one person might have to "filter" through. This means a BI of 2.45 is
far greater than it seems.

Personally, I (1.) like some of the stuff Cor posts, and (2.) only subscribe to the
'alt.ham-radio.vhf-uhf' NG, so I don't see so much of the same thing. I used to subscribe to
ALL of the 'alt.ham-radio.???' NGs, but it was too much repetition.

Hi Doc. I'm not sure that I would spend the equivalent of $300 on a triband HF beam and a tiltover crank up lattice tower let alone a bag full of wire and a couple of dog bones. My 10m vertical is a retuned 5/8y CB antenna salvaged from a house remodelling. I got 10M of Mil Spec RG213 attached as well, all free for the asking. My 10m dipole is made from 8mm copper microbore CH tubing and the connector insulator from a discarded UHF TV antena. They both do all I ask of them and they cost no more than pocket change for connectors at the shack end and a scotchbrite pad. I did buy a triband collinear for 6/2/70cm in a glass fibre tube due to restricted space and someone turning up with ladders a week earlier than expected, but since then, I've managed to stack a pair of 2m folded dipoles salvaged from a 2m crossed yagi and it's outperforming the commercial collinear just hanging out of the window on a bit of string.

When I get around to it, I'll buy a wire pack and build my own atennas. I might have fathomed out the math to complete my 20M hammock by the time I get back home. In the meantime, I need to do some serious studying on the subject of current and voltage baluns for the longer antennas I have planned. Do I make the windings clockwise or counterclockwise in the Northern Hemisphere?

It's not me who is saying every 1/2WL is the same for both antennas
so I don't know how to locate the same point.

Well, this is clearer than what you wrote earlier, as they have
included the "on port 1" part, whereas you stated just "incident
reflected", which told us nothing.

I stated: If ..., PA's will always re-reflect 100% of the incident
reflected power. That's obviously reflected power incident upon
the PA.

Just because you don't understand someone doesn't mean they are
wrong. But it's easy to give up trying to understand people if you
want to maintain the illusion that you are All-knowing.

From Pozar's Microwave Engineering:

Reflection Coefficient = (Zl-Zo)/(Zl+Zo)

Where Zl is a purely real load impedance, and Zo is the
purely real characteristic impedance reference.

When you change Zo, you change the normalized center of the
Smith, and therefore the Ref. Coeff. and SWR, looking into the same
load.

The Smith Chart is an extremely powerful graphical RF tool, which
has become part of the basis for communicating in the RF world, as
well as a standard for displaying impedance on most RF measuring
devices.

You need to read up on this if you want to understand me.

Even when the other person is correct too? I think it IS an ego
trip if you can't admit someone has a point, and are too scared to
discuss it further for fear of looking weak or exposing a lack of
knowledge about something.

>
> (*) For example, have you ever looked up the equations for calculation

Richard,

It always astounds me how the technically challenged are wont to launch ad hominem attacks instantly when matters evidently beyond their understanding, or perhaps in disagreement with their preconceived notions and prejudices, are brought to light.

I note that not a single statement that I made in my posting is either declared incorrect or is replaced by your version of "truth."

All I read is a lot of disconnected, poorly conceived and worded "slams" at me for posting the piece in the first place.

The note was addressed to Ian who points out that he agrees totally with everything that I said. Why not select him as a target as well ? Double your pleasure with two targets! And, of course, appear the fool twice for making such an inane posting in the first place.

Further to the point, no one has offered a single word of disagreement with the factual content of the posting. Only you have felt compelled to take your valuable time to post nonsense mouthings having nothing to do with the subject matter.

Richard, in the past I have had a small degree of respect for your postings and your viewpoints, but if this is the best you can do now, then clearly it is time for you to resume your meds.

Historically, you seldom if ever contribute anything of substance to a discussion but rather tend to sit on the sidelines making learned comments about the abilities of the participants to present their material and the degree to which they fail to meet your high standards for discourse.

Yep, time for the meds . . .

Or, perhaps you could actually contribute something of value by telling us where my posting is in error in *fact*, not in error for having been posted. I presume that you feel capable of tackling that chore.

But, you are right about one thing: if you are an example of "us folks" then I am definitely not one of you, and very proud of it.

Source record: 110478

Ok, I'll try once more.

Look again at what I wrote earlier:

>No, you won't see a change in the SWR at point 1 as you change the PA
>> impedance. All the fiddling you do with your Smith chart just won't
make
>> it happen. Sorry.
>>
>> The SWR, voltage, current, impedance, power, reflection coefficient,
>> waves, or anything else don't change in response to your Smith chart
>> exercises.
>>

To which you replied:

> Absolutely incorrect. Time for you to review your Smith Chart
> again.

Here's an experiment for you to try.

On your workbench, measure the characteristic impedance of a cable, or connect it to a source or load and measure the SWR on it. Now go over to your desk, take out your grease pencil, and change the reference impedance of your Smith chart. Go back to the bench, check the SWR and the cable Z0. Has it changed?

If the answer is yes, I'll admit having a serious shortcoming in my knowledge of the power of the Smith chart.

If *you'll* review the Smith chart again, you'll find that *if* you set the reference impedance to the Z0 of the transmission line you're analyzing, then the SWR, impedances, and so forth that your read from the Smith chart are correct. If you set the reference impedance to some other value, an SWR read from the chart certainly isn't the SWR on the transmission line.

Z0 in the equation you quote refers to the characteristic impedance of a transmission line. If you change the impedance of the transmission line, given the same load impedance Zl, you change the SWR, as the equation indicates. (Changing the reflection coefficient changes the SWR on the line.) But changing the reference value on your Smith chart doesn't change the characteristic impedance of the cable.

Now let's see what you wrote this time:

Dr. Slick wrote:
> . . .

> When you change Zo, you change the normalized center of the
> Smith, and therefore the Ref. Coeff. and SWR, looking into the same
> load.

Yes. When you change the line's Z0, you should change the normalization
of the Smith chart. But changing the normalization of the Smith chart
doesn't magically change the cable dimensions to give it a
correspondingly new Z0. (Or does it? Something I'm missing here?)

> The Smith Chart is an extremely powerful graphical RF tool, which
> has become part of the basis for communicating in the RF world, as
> well as a standard for displaying impedance on most RF measuring
> devices.
>
> You need to read up on this if you want to understand me.

Thank you, although I'm not an expert at using the Smith chart, I know
my way around the circle. But perhaps more study would reveal the
mechanism by which changing the chart reference causes spontaneous
redimensioning of the cable.

> Even when the other person is correct too? I think it IS an ego
> trip if you can't admit someone has a point, and are too scared to
> discuss it further for fear of looking weak or exposing a lack of
> knowledge about something.

All right, I was scared to admit that you have a point, that all you
have to do to change a line's SWR is to go over to the desk and change
your Smith chart. But I've overcome my fear now, and am exposing my
ignorance, or weakness as you say, for all to see.

I'd like to learn more about the mechanism, though. When you renormalize
your Smith chart, is the line's Z0 changed by a spontaneous change in
inner conductor diameter, outer conductor diameter, dielectric
permittivity, or some combination? Is it some sort of telekinesis, or
perhaps something to do with Chi? I never could quite get the hang of
Feng Shui, so maybe that's it. I can't find any reference to the
phenomenon you're claiming in my engineering texts -- perhaps an occult
or New Age bookstore would be more fruitful?

> From Pozar's Microwave Engineering:
>
> Reflection Coefficient = (Zl-Zo)/(Zl+Zo)
>
> Where Zl is a purely real load impedance, and Zo is the
> purely real characteristic impedance reference.
>
> When you change Zo, you change the normalized center of the
> Smith, and therefore the Ref. Coeff. and SWR, looking into the same
> load.

Almost right, but a misplaced "therefore". The reflection coefficient
and SWR don't change because you change the Smith chart normalization.

They change because you've changed the cable's Z0. If you know how to use a Smith chart correctly, you can then go and renormalize your Smith chart to the new Z0 (as you've said), and from it you can read what the new reflection coefficient and SWR are. Or you can forget the Smith chart altogether and measure them, or calculate them from an equation. But if you normalize your Smith chart to some value other than the cable's Z0, you're no longer reading the transmission line impedances and SWR from it.

It sure looks to me like you're confusing reality with what you read from your arbitrarily normalized Smith chart. They're not the same. Just like the reading on an SWR meter isn't the same as the SWR on a transmission line of a different impedance. And actually for exactly the same reason. Hm, maybe that provides even one more way to say it. Set up your source, cable, and SWR meter like you have it in your earlier posting. Replace the 50 ohm SWR meter with a 75 ohm SWR meter. Renormalize your Smith chart for 75 ohms. Presto! The SWR meter reads the same as the Smith chart! But y'know what? YOU DIDN'T CHANGE THE SWR ON THE TRANSMISSION LINE. Put the 50 ohm SWR meter back in just on the load side of the 75 ohm one. It reads just the same as it did before, and it's reading the actual SWR on the 50 ohm line between it and the load.

Again, changing the Smith chart's normalization does not change a cable's Z0 or SWR. Feng Shui and voodoo notwithstanding.

A Smith chart is simply (not to disparage in any way its ingeniousness or utility) a polar plot of reflection coefficient on a special scale. (The trick is, of course, generating the scale, an exercise in conformal mapping I recall doing in fields class.) Check it out -- measure the length of the vector from the center to any impedance point (with the chart radius equalling one), and the angle from the main axis (zero ohms being the positive direction), and you'll see you have the reflection coefficient.

I can't figure out any more ways to say this.

I am always interested in learning. I don't use a Smith chart a great deal, but I know Tom Bruhns, a regular poster here, does. I'll gladly defer to him on issues of Smith chart use, and hope he'll feel free to correct me on any errors I've made in the above discussion -- as he has a number of times in the past, and which I've greatly appreciated. Walt Maxwell, an occasional poster, is truly a Smith chart expert, and I'd also welcome any corrections or amplifications he'd care to make. Or any other knowledgeable Smith chart user.

Source record: 110479

Among the posters on this topic, I'd be willing to bet a substantial sum that at least Tom, Ian, Cecil, Bill, and I can recite that formula from memory. In addition, there are a number of other regular and occasional newsgroup posters in this category who've been wise enough to not having posted on this thread, and some who have posted whom I don't know well enough to put my money on. I'd be willing to further bet that Ian, Cecil, Bill, and I could have done so at any time for at least the last 20 years. I omit Tom from this second list only because I haven't yet met him in person and otherwise haven't gotten any hints of his age -- but I'll take a gamble and spot him 10 years at least. Furthermore, we all know how to use it, and have done so countless times in the process of designing systems that work.

I'm glad you've discovered this equation. Learn what it means and how to use it, and you've taken a good first step toward understanding transmission line phenomena.

Yes - have you already discovered the special tricks for fitting N plugs
to 103, or do you need that information?

(It would be dead simple to show you, but would take a lot of words to
describe.)

but I brought my snorkel. ;-)

>
>73/72, George

Hi George,

If you suffer the heat of taking a stand, so much for a test of faith.
I have not seen you respond to the chain of evidence I have supplied
to these matters. I will offer that this body of work long preceded
my missive. You might or might not find that work
interesting/correct/or worthy of your attention, but that does not
erase if from the archive nor detract its intrinsic merit in desired
measure to bruised ego.

Pick any ONE of your cherished notions that I so soiled and put it up
for a clear and concise examination.

OR

Let me head that off with a very simple question that most dodge; and
in fact lies at the very heart of your subject line:
Given the premise that the amateur's rig output Z is NOT 50 Ohms, what
value does it have (cite any assembly of conditions)?

You will no doubt get many thumps on the back from well-wishers who
spit in my direction. How many will offer a numeric response to that
technical enquiry? I can forecast that will stand at the current
exchange rate of 0. I will also forecast there will be either total
silence, or scattered muttering about why they wouldn't engage such a
scurvy fellow as me. And yet the absence of that number from the
discussion under this subject line mocks the charter of this group
more than my humor did you.

Is it lower than 50? Higher than 50? How much? The stunned silence
in response to such simple, forced speculation is more a result of
intellectual catatonia than moral indignation.

Those who have offered numbers (I count among them), who have revealed methods of their derivation (I count among them), who performed actual bench work (I count among them), who offer rationale as to the subject's correlation to other observables (I count among them) is notable in contrast to those who have nothing to show but the shallow rhetoric of impotent denial.

3338. QRe: Make your own hardline?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-16 12:01:36 UTC
From: Phil <philip.bradway@verizon.net>
Message-ID: <A2p%a.2299$N37.960@nwrdny02.gnilink.net>
Source record: 110481

I've made a short section (12") of hard line for a MW dish feed. It's no easy task! size relationships are critical and there's no easily available material for the center conductor the right size for 1/2" copper pipe. I ended up using hobby brass tubing for the project. The transition between the center conductor and the connector is a bit finicky, too. Forming the taper is a pain! The return loss is 7 at 3gHz, not great, but usable. In short, the suggestions about CATV hard line are good ones, The 3/4 " works up to 5 gHz with reasonable losses and that's with home brew connectors.

Good luck!

Dr. Slick wrote:
> How would you explain what Cecil wrote? How are some people
> improving SWR by changing coax length, when in theory they shouldn't
> be able to do this?

If I were using a 450 ohm SWR meter on 450 ohm Z0 feedline, the SWR meter would indicate no change in SWR as I change the feedline length. Assuming the 450 ohm SWR meter is accurate, the indicated SWR and the actual SWR are the same.

When I use a 50 ohm SWR meter on 450 ohm Z0 feedline, the SWR meter is NOT indicating the true SWR on the 450 ohm feedline. It is indicating what the SWR would be if the line were Z0=50 ohms. All it is indicating is the impedance seen by the transmitter which indeed does change with feedline length in a system with reflections.

Theoretically, the SWR on a feedline changes only slightly with changing feedline length and that is because of additional losses in the feedline as the length is increased.

Correct! What Roy is objecting to is the wording of an assertion of
yours that seemed to imply that changing the reference Z0 on a piece
of Smith Chart paper magically changes the physical Z0 of the transmission
line to a different value. As you have advised me, be careful of what you
say and how you say it.

I referred to "free space" the other day. The image I had in my own
mind was the free space halfway between here and Alpha Centauri. Others
had the image of "free space" as 0.001 WL away from a radiating antenna.

Either Pozar (who I've never heard of) is not quite correct or Dr Slick has misquoted him or taken him out of context.

In fact, the equation is also true for complex values of Zl and Zo. The angle of RC can lie in any of the 4 quadrants. Furthermore, the magnitude of RC can exceed unity.

I offer no references in support of this statement. It is issued here entirely on my own responsibility.

Thanks...I think...<:-))

All put up by hand...Mine...with the aid of a friend pulling on the rope to the gin pole now and then. Took something like 2 to 2 1/2 years to finish. When I started I figured maybe a couple of months.

"One of these days" I plan on going up there and shooting a panorama and then stitching the photos together. I've done several partials, but I really need to fasten the camera to the mast and then turn the thing maybe 20 to 30 degrees for each shot.

I gotta take the mast out of the rotor, the rotor out of the tower, then unbolt the tribander, hook up a come along, loosen the thrust bearings and THEN let the mast down to the point where I can work on the 6 meter antenna . The boom support came loose and now just lays on top of the boom instead of holding it up. No problem for wind, but if we get any ice it'll be all done.

As long as I have that much to do, I will probably lower the whole works down to where I can replace the pig tails from four antenna systems. I don't know if I'm going to leave the vertically polarized 144 and 440 arrays up, or just replace them with a "repeater" duo band vertical and lower the top of the mast by 14 feet.

The only machine work was digging the holes for the guy anchors. It took me two days to dig the one for the tower base and I had lost all desire to dig three more about 2 1/2 times that size. The guy that dug the holes "with a back hoe" shown in the photos, had a pole he could fasten to the bucket on the front and he used that to carry the guy anchor posts and set them in place. It was well worth the price.

<snip>
>Ya take the vertical antenna & mast load out with a thrust bearing

>either in the top plate or somewhere close to the top, run some loosly
>guided 2-3" EMT down the tower and . . . does a great job of knocking
>down the torsional start/braking/wind spikes throughout the system AND
>reduces the number of climbs. A second thrust brg just above the
>rotator is even better. I dunno where they come from.

This is pretty much the way mine is set up, except I use both 1 1/2
and 2 inch steel tube with 1/4 inch wall. Thrust bearing at the top
of the tower and one just above the rotor which is about 25 feet or so
down in the tower.

I didn't want to run the steel tubing all the way to the ground as
with this antenna load it would get pretty "springy".

The ROHN 3" thrust bearings are "about" $80 to $85 each. Maybe more
now. You can get them from quite a few distributors. Mine came from
Texas Towers. The tower itself was a closeout from Michigan Radio
down in MtClements MI.

Another "one of these days" I'd like to replace the steel tubing with
1/4 inch wall chrome molly. Tis expensive, but I'm not going to be
able to keep climbing forever. (although I'd kinda like to think so)

Wellll....

The stuff isn't that difficult to make.
Making it correctly is something else.

OTOH, with half inch I think you will find the loss is not as low as
you have been thinking.

With half inch connectors are fairly simple to make.
Splices are also relatively easy to make if you have a lathe.
The commercial stuff uses gasketed brass rings with at least 4 screws
through the flanges to hole the sections together. The center
conductor can be joined using a threaded fitting, or just soldered
with the outer conductor slid back.

BUT as to the practicality of using hard line...
You need the proper spacing for the spacers
Breakdown voltage is less than for coax cable the same size with foam
or solid dielectric.
Copper oxide will become a problem unless the feed line is "purged"
with dry Nitrogen.

Typically the coax is *almost* air tight. It is purged with a very
low flow and pressure of dry Nitrogen. IF the flow increases and or
the pressure drops you know three is a problem.

Don't purge it and it *will* develop problems sooner or later. If you
live in a hot dry climate this might not be much of a problem.

IF you make your own, it will probably still cost twice as much as
good coax.

IF you are looking at saving money, or coming up with a good "low
loss" cable try (as others have already suggested) the 75 ohm TV hard
line. It's usually free, works great, you can easily find 1/2 inch
and 3/4 inch. I understand 1 inch is also available.

It's relatively easy to make connectors for the 1/2 inch and 3/4 inch.
I'd think the same approach used for the 3/4 inch would work for the 1
inch.

The only drawbacks are the difficulty of making short radius turns, care in handling it, and the 1/2 inch is relatively fragile. The 3/4 inch and up is pretty rugged but still requires care in making bends or it will easily "kink" which pretty much renders that piece useless.

The value of a computer program resides not in the source code language but solely in the Reliability of the programmer.

And Reliability is a measure of Quality versus time.

And Quality is the extent to which a product conforms to pre-specified requirements.

Hi Cecil,

50 Ohm. The BVT has been calibrated long before this application (8
years ago the first time) without surprises. Methods are described in
Walt's Book, Reflections. I suggest you use his software rather than
roll your own. I would also suggest you consider his methods as well.
Point in fact, I followed his advice to measure at odd 8th wave
intervals if I recall his instructions correctly. If not, it was "by
the book." I also performed the calibrations at the remaining
cardinal points. Tedious perhaps, but having done it through maybe
three or four times without outliers, I don't expect there is any need
to visit that again.

I don't recall Walt ever writing any statistical analysis software.
All my program does is take your raw data and try to make sense of
it using statistical analysis methods. It would be a near-perfect
SWR spiral on a 40 ohm Smith Chart. Seems that might be a clue.

Funny that you request responses, nay, demand responses, and then dismiss them out of hand. The data indicates an impedance incompatibility between the transmission line and the measuring instrument. Your results are perfectly compatible with an SWR spiral on a 40 ohm Smith Chart including the loss in the feedline.

An additional source of VSWR error exists. It is of interest to the purist.

If I provide a perfect 50.000 ohm dummy load for typical JAN-C-17 RG type cable, example RG-9913, I have to design for a maximum VSWR of 1.06 to 1 due to tolerances in the cable!! So, I'll have a minor variation in observed VSWR as a function of length.

Same applies to the design impedance of your VSWR meter. It has a tolerance on it's 50 ohms!!!!!

Cecil,

Suppose I do the following experiment: a source of unknown impedance, connected to a shorted 1/4 wave line through a ~50 Ohm series resistor. When looking at the voltage on the two ends of the resistor with a 'scope, I expect them to be the same value, with no phase difference. Do you think that would be enough to satisfy the nay sayers that the source is delivering no power? I am *not* talking about you.

In retrospect, my posting here is probably a variation of what Roy posted a few months ago. Didn't mean to rip him off. BTW, I was in error when I said the line charges up in 1/2 cycle; that would be true only if the source impedance was 0.

At 6 meters you will not notice any improvement and maybe even some loss .
Just use some good low loss 1/2 inch size coax. It is difficult to make
low loss open wire work above about 30 mhz.

3356. Re: Make your own hardline?

Newsgroup: rec.radio.amateur.antenna

Source record: 110500

I remember one case where making coax was done and was appropriate. It
was a line that was several inches in diameter and probably no more than
20 meters long. The purpose that it served was to "feed" an end-fire
array of loop receiving antennas (along the line's length). The reason
to use the line was to have a VF that was as close to 0.99 as possible
so as to phase the distributed elements as optimally as possible.
Attenuation and power had nothing to do with the issue.
The result was a unidirectional pattern. One in each direction
depending on which end one connected to. Three of these fellows (and
six connections) made a reasonable direction finder with an
instantaneous beam every 60 degrees.
Life is much too short for one to use anything other than Heliax (or
TV cable) for the "normal" radio uses.
73 Mac N8TT
P.S. The fellows who replicated the Luxemburg effect with extremely
high power were said to have made their transmission lines out of
irrigation pipe. They must have had much more time than money.

Why don't you make the open-wire line an even number of half-wavelengths?
Then all you need is a 1:1 choke at the transmitter. No loss in the
baluns at all because there aren't any.

It doesn't report that. It is a data reduction, curve fitting program.

> What does your software report for calibrating a software 50 Ohm line
> feeding a software 50 Ohm load?

It doesn't report that. It is a data reduction, curve fitting program.
The only input to the program is your data.

Consider that with your 16.67 ohm load, the impedance 1/2WL away from
the load should repeat. But the minimum reflected power point indicates
a load of about 25 ohms. So there's one error already, perhaps caused
by the diode. If you plot your data as SWR points on a 50 ohm Smith
Chart, it is obvious that the SWR circle (spiral) is compressed at the
lowest reflected power readings. It is also obvious that the center
of the SWR circle is not the center of the 50 ohm Smith Chart. That's
a pretty clear indication that everything is not 50 ohms. If full scale
on the Bird is 5 watts, the readings can be off by 0.25 watts. 0.45
watts plus or minus 0.25 watts is not very accurate.

Hi Cecil,

I now understand that you are using regression analysis and not
engineering computation code similar to that Walt has published.

What does your software report for a software 40 Ohm line feeding a
software 50 Ohm load? That is, when all data points (that is each
increment of 1 foot) exhibits 0 Watts returned for 5W applied?

What does your software report for a software 50 Ohm line feeding a
software 50 Ohm load? That is, when all data points (that is each
increment of 1 foot) exhibits 0 Watts returned for 5W applied?

Feel free to cast in your suggested 5% FS error to force the worst
case scenario for the calibrations.

My software takes a list of reflected powers, assumes the forward
power is five watts, calculates the 50 ohm SWR for each point, and
plots them every 0.03WL on a Smith Chart. It was written to accept
your data points. If the reflected power above was always zero watts,
all those points would be the same point, i.e. a circle of zero radius
at the center of the Smith Chart.

Take time to plot those 50 ohm SWR points on a Smith Chart with the
0.45 watts reflected point assumed to be the lowest purely resistive
point. A picture is worth a thousand words. I have seen that picture
before. It was when I designed my SWR meter for a Z0 of 450 ohms and
my window-line turned out to have a Z0 of 388 ohms.

Hi Cecil,

Thank you. I see that for the 50 Ohm load that the line exhibits a
characteristic of 50 Ohms as described by its concentricity about the
reference.

This confirms the indication of 0W returned for all settings when
applied to 4 different 50 Ohm loads. One load is calibrated and
exhibits an S1 of 1.0061 (this is from a set of data points every 5Mhz
to 1 GHz). The other loads are of equal caliber.

This confirms the vendor MicroCoax specification for UT-141-A:
50 ï¿½1 Ohm
OD 0.141 +0.002/-0.001 (0.142 measured)
ID 0.1175 +/-0.001 (0.1175 measured)
Conductor OD 0.0359 +0.0010/-0.0004 (0.035 measured)
Dielectric PTFE

This is no surprise given the cable is premium short run (length, not
reels) material specified out to 20 GHz (from Boeing's precision
electronics facilities). I have several hundred feet brand new.

Your idea will work just fine. The J-pole is a wide-band antenna and the only adjustments needed is the coax tap point (or gamma adjustment if you're using that type of match) but as long as your swr is reasonable, leave it alone.

Message-ID: <vjuj3pjm4ftn57@corp.supernews.com>
Source record: 110510

There's nothing wrong with the formula or the context. It follows from a straightforward derivation that begins with the ratio of reflected to forward waves at the load, and results in satisfying the boundary conditions and Kerchoff's voltage and current laws at the load. It holds for any complex values of Zl and Z0. The resulting reflection coefficient is of course complex, but it's often confused with its magnitude or with the time domain reflection coefficient. Increasing this confusion is that there's no standard notation for these terms, so the complex value in one text might be denoted by the same character as the magnitude in another text.

There's no problem with the reflection coefficient having any angle in any of the four quadrants. However, I've frankly had trouble getting around the notion of the magnitude of the reflection coefficient being greater than one with a passive load. I know it sometimes happens with active loads, and there are even Smith chart techniques to deal with it. You'll find discussions of it in texts on microwave circuit design.

It looks like it's possible to get a reflection coefficient with magnitude > 1 any time Rl*R0 < -X*X0. Reg recently posted some values of Z0 for common coaxial cables that show the angle of Z0 approaching -45 degrees at low frequency. So it wouldn't be hard to envision a cable with Z0 = 100 - j100 or thereabouts at some very low frequency. If we were to terminate it with a pure inductor with 100 ohms reactance (Zl = 0 + j100), it looks like the reflection coefficient would be -1 + j2, which has a magnitude of the square root of three, or about 1.73. What does this mean? It means that the reflected wave has a greater magnitude than the incident wave. I'm not sure there's anything wrong with this -- it's sort of like a resonant effect. It would have to be checked to make sure that the law of conservation of energy isn't violated, and that Kirchoff's laws are satisfied, but I'd be surprised if there were any violations. The calculated SWR is negative, but that's pretty meaningless considering we have a line with a huge amount of attenuation per wavelength (in order to have such a highly reactive Z0). With that kind of attenuation there's no danger of having an oscillator with no power source.

I'd really like to hear from some of the folks who deal more frequently with reflection coefficient than I do, to see if I'm on the right track, or if there is some consideration that requires modification of the equation for very lossy lines. I've got quite a few references that deal with reflection coefficient. They all give the same formula without qualifications, but none mentions the possibility of the magnitude becoming greater than one.

Reg, you've got more experience with very lossy lines (in terms of loss
per wavelength, which is what counts here) than anyone else on this
group. What happens at the load if you terminate a 100 - j100 ohm Z0
line with 0 + j100 ohms?

How about looking at the voltage across the resistor? i.e. the difference
between the voltages at each end of the resistor?

Please plot your data on a Smith Chart. Since your data is
obviously nonlinear, I would suggest diagnosing the nonlinearity
problem before concluding anything. For instance, what is the
one tenth scale RF RMS voltage before it is rectified by the
diode?

This may not be a good analogy, but Specific Impulse of rocket motors
helps me to remember that the 'units' of something have to be considered
in the context of what is being measured. Specific impulse is a measure
of the performance of a rocket motor. It measures the thrust obtained
from a single kilogram of propellant burned in one second. The 'units'
of Specific Impulse are seconds, but we're not measuring 'time'.

The spacing of 450 ohm window-line might be better for 6m than the
3"-6" spacing of open-wire line.

Hi Cecil,

That is the whole point of Mismatch Uncertainty. What you call
nonlinearity is the NBS documented conclusion of the mismatched
conditions at both ends.

Feel free to investigate and enquire further about your concern over
nonlinearity.

PA----+----50 ohm line----+SWR meter+----50 ohm line----+50 ohm dummy
load
1 2 3

Once again, if you placed an SWR meter of the same output
impedance of the PA at point 1, you will measure the SWR at point 1,
and it would be akin to re-normalizing the Smith. Change the PAs S22
(and the impedance of the SWR meter, and you will definitely change
the SWR at point 1. Do you agree with this?

I've already agreed with you that the SWR at point 3 won't change
in theory, as it is surrounded by 50 ohms. What is it about this
simple concept that you cannot seem to understand?

It's clear that you needed to be informed of how this relates to
re-normalizing the Smith Chart, which is what you are doing be
changing the reference impedance. Get the free program MIMP, and you
can investigate this yourself.

Investigate more, Roy.

In addition, there are a number of other regular and occasional
> newsgroup posters in this category who've been wise enough to not having

>

I agree this is a very obvious and standard equation, which
applies to the re-normalizing the Smith. But you obviously don't
understand how changes in the Zo will change the SWR going into the
same load, which can be simulated on MIMP by changing the value of the
center of the Smith (called re-normalizing).

Since when was 50 Ohms ALWAYS a 1:1 SWR?

Slick

Hi Tad,

Your point is well taken. ALL physical phenomenon can be expressed
through a chain of conversions in the MKS system of units. When
someone tells you that their terminology is inconsistent between
disciplines (as such offered in this and other threads); it must then
be amenable to reduction to MKS terms or one of the two conflicting
expressions is invalid.

That is to say to the specific matter about the usage of "ohms:"
Here, the unit of ohm must be reduced to Meters, Kilograms, and
Seconds for both usages (electrical and radiative). At that point,
both will have a common basis for comparison and if in fact their
reduced terms are identical, then their common usage is also
identical.

One simple example is with the measurement of body weight on the
bathroom scale (a torsion or compression device) as opposed to the
weight measured on the doctor's scale (a beam balance). Let's say
before you go to the doctor's, you weigh yourself in around 165
pounds. When you arrive at the doctor's, his scale says you weigh
around 75 kilograms.

Let's remove this same scenario to the moon (you live in one of those
futuristic 1990's colonies forecast by the space race back in the

60's). Before you went to the doctor's you weighed in around 33 pounds. When you arrive at the doctor's, his scale says you weigh around 75 kilograms.

Here we find the expression "pounds" suffers what appears to be the same plight of "ohms" in that the determination of a value is inconsistent. You may also note constants of proportionality on earth and the moon. These constants when expressed as a ratio also describe the significant differences between the earth and the moon.

The problem is that the term "weight" has a hidden association to the constant of Gravity. The expression Gram is one of Mass, not weight. The expression pound is not an expression of Mass unless you expand it to include the term for the particular constant of Gravity. Mass is constant in the Newtonian Universe, and weight is not.

If you were to have reduced the pounds to the MKS system both times, you would have found it consistent both times (here on earth, and on the moon).

If you reduce the "ohms" to the MKS system both times.... Well I will leave that for further deliberation as some are sure to be surprised. :-)

[s11]**2 + [s21]**2 = 1

For a lossless passive two port network, where the brackets
indicate magnitude only.

If you find a passive network that reflects more voltage than it
receives, let us all know about your free energy device.

Reflection coefficients greater than unity, which go outside the
Smith, only happen with active devices, as you have mentioned above.
Stability circles are a related topic, as their centers are often
based outside the unity RC circle.

How about CATV hardline? I'm using about 70 feet of the stuff for
6M and 2M. I'm using the 1/2" stuff for 6M and the 3/4" for 2M.
It should be FREE -- the Most Important cable characteristic. HI!HI!
No reason why you couldn't use the 3/4" stuuf on 6M -- tho', I think
it might be overkill.
As another posted mentioned (for open wire), you can cut it for
n-multiple 1/2 wavelengths, and use the Flexible Stuff for pigtails
at each end.

> cantilever beam.
>

I agree with the essence of Brian's observation. However, I offer two additional observations:
1. The engineering understanding of tall columns using steel has gone through quite an evolution in my lifetime. Buckling of a vertical cantilever beam (A.K.A. a column) is a different issue from the breaking of an actual cantilever beam. Need to study the latest steel handbook and the tower standard and use an appropriate safety factor that is larger than 1. [Yes, the latter is a snide remark. People do sell stuff with specifications that are accurate for a safety factor of one!]
2 The engineering understanding of the effects of wind has also undergone quite an evolution. See the tower standard (222F, I think is the last one published). Any simple relationship between "miles per hour" and pressure is almost certain to be inappropriate. [Do not believe most antenna manufacturer's survival ratings in terms of MPH.]

However, for the heights being discussed, the "roughness" of a typical urban neighborhood will significantly reduce wind loading from what one would expect using weather wind info. That fact provides an additional safety factor that just does not exist where I have placed antennas and towers.

I give a big Amen to Brian's observation that even EEs should be able to run the numbers AND a big Amen to the need to run the numbers. This is an area where one wants to check twice - or more.

I havn't been following the discussion very closely.

But does your statement imply a reflection coefficient with a magnitude greater than unity cannot exist when only a passive transmission network is involved ?

I've agreed with you on the semantics of antennas as transducers,
but two transducers DO make a transformer.

Ohms are still always Ohms, regardless of what you are measuring.
And it's very interesting that the E and H fields have units of
Volts/meter and Ampere(turn)/meter, which when you divide one by the
other, you get basically Volts/ampere, just like you would in a
transmission line.

But I don't claim that a wave traveling in a transmission line is
the same as a wave traveling through free space.

Hi All,

I note by the absence of response that at least my mystical powers of clairvoyance are unparalleled. No one dare step up to the bar to answer the question:

"What is the Z of a transmitter, if it is not 50 Ohms?"

For those who would rather argue the mystic ability than answer the question, I will allow that this same absence may be due in part to the Blaster virus and the power black out. Now that I've braced up your crutches, let's proceed with a telling example of both the academic principle and the practical implication.

I will simply choose a value for you. In other words, we will venture where these angels fear to tread. We will start with a deliberately mismatch transmitter, and a deliberately mismatched load. We will then throw in the practical necessity of line loss and ask the question that is my acid test for the wide-eyed inventors:

"Does it make more than 1dB difference?"

The scenario begins:

"A 50-Ohm line is terminated with a load of 200+j0 ohms.
The normal attenuation of the line is 2.00 decibels.
What is the loss of the line?"

Having stated no more, the implication is that the source is matched to the line (source Z = 50+j0 Ohms). This is a half step towards the full blown implementation such that those who are comfortable to this point (and is in fact common experience) will observe their answer and this answer are:

"A = 1.27 + 2.00 = 3.27dB"

"This is the dissipation or heat loss...."

we then proceed:

"...the generator impedance is 100+0j ohms, and the line is 5.35 wavelengths long."

"A = 1.27 + 2.00 + 1.62 = 4.9 decibels"

Thus the answer to my question is:

Yes. 1.62dB is greater than 1dB.

Now, as to the application of this knowledge to the typical user. It becomes: "does my standard of 1dB meet the thresh hold of your caring?" Perhaps not and even 3 dB may be of no concern. For such folk I offer my best wishes and we each proceed happily on in life. [This, of course, presumes they do not in fact have a rig that exhibits a 600 Ohm output Z and hence the danger of nay saying the obvious without expressing a value to replace it.]

Now, as to the application of this knowledge to the critical user. By this I mean those here who want to have a complete answer, and being thus informed can make their own choices. Is there anyone corresponding here that want to dispute that this is the charter of this group?

I have then twice shown how a transmission line being bound by two reflecting planes introduces a Mismatch Uncertainty. This example has enlarged on that slightly through my advice that this uncertainty can be reduced to zero through the description of all paths. As I have also pointed out in the past, this is a simple truism of wave interference math - very simple.

The fact of the matter is that nearly every correspondent to this forum employs a transmitter designed to and exhibiting 50 Ohms source Z. The simple fact of the matter is that none of those same correspondents will typically encounter that additional 1.67dB because of this. Those who choose to operate their transmitter outside of this specification may; but those same operators rarely, if ever, examine the evidence of Mismatch Uncertainty because they never move their load nor their SWR meter (the path never changes). They instead will observe a reading in their complacency and accept the error without being aware (unless they have read this, that is).

I will add that even when operating outside of the characteristic source Z, that is not significantly off enough to match the issue portrayed above unless you cut power dramatically - and even then the issue is moot even though the loss is not.

So, part and parcel to the subject header above and having shown how ignorance and rejection of the obvious has a concomitant loss; the question, as always, remains:

>Given the premise that the amateur's rig output Z is NOT 50 Ohms, what
>value does it have (cite any assembly of conditions)?

What constitutes the silence from this point on? My proven clairvoyant skill being elevated by the day, the Blaster virus, the power outage, or that same intellectual catatonia?

Absolutely not. The SWR meter will measure the SWR at point 1 only if
it's the same impedance as the *line*. If the PA has a different
impedance than the line, and the SWR meter has the same impedance as the
PA, it will not be reading the SWR on the line.

If you want to use a Smith chart to see what the SWR is on the line, you
must normalize it to the impedance of the line. Change the PA impedance
all you want. Change the Smith chart normalization all you want. Neither
will have any affect on the SWR on the line. Changing the meter
impedance won't have any effect on the SWR on the line, either, although
it'll change the reading on the meter so that it's no longer indicating
the SWR on the line.

>point 1. Do you agree with this?
>
What exactly do you think you mean by "change the SWR at point 1"? All you have done is to replace one SWR meter by a second one that has been calibrated for a different system reference impedance.

You had to *choose* a value for the new reference impedance in order to pre-calibrate that second meter. When you re-normalize the Smith chart, you choose the *same* new value. So of course the SWR reading on the second meter is going to be the same as you'd calculate by re-normalizing the SWR1 circle on the Smith chart from Z1 to Z2.

If that's all you ever meant, we've spent a week homing-in on something that is totally obvious.

The only other problem with your example is that by mentioning the PA's S22 value, you seem to imply that it is relevant. It isn't, because variations in the source impedance will not change the SWR reading on either meter. Only the load impedance can change the SWR.

Now take away all the coax and move the 50-ohm load to the outputs of the respective SWR meters. The indicated values of SWR1 and SWR2 will be exactly the same as before.

Nobody knows and nobody cares. All voltage to current ratios are determined by the system outside of the transmitter. The only thing a transmitter need furnish is a voltage (or current or power). No matter what the output Z of a transmitter, it can put out a voltage (or current or power). What happens inside a transmitter doesn't affect anything except transmitter efficiency.

Any coherent energy re-reflected inside the transmitter simply superposes with the forward wave and becomes indistinguishable from the generated power. If modulation is added and the feedline is long enough, the re-reflection could be detected. With an unmatched TV generator and about 1000 ft of open-wire line, the TV ghosts would give an indication of how much reflected power is actually re-reflected inside the generator. For those who assert there are no reflections from a generator, this would be an easy experiment to run.

Yuri,
I think you would better understand what is happening
if you view the inductance in question as half of
a transformer, where the other half is the aether.
This allows you to bring in the formular NxI one side =
NxI the otherside. This way you can see that I is constant.
If it wasn't a constant then the lines of flux would have a
very distorted shape at one end of the inductance.
The fact that transformers have impedances that are not
totally resistive is because of other factors than Inductance.
If I am incorrect with this analogy I would apreciate any
corrections as I am sure Yuri would to

Hi Cecil,

Feel free to attempt it. You are one of the more qualified to do this
by having a variable transmission line like mine.

As a more approachable test, not involving line variation, but simply
knowing its length, and one that includes your expectation of line
loss consider the correspondence of my responses to George, W5YR, in
the thread "Internal Resistance (?)."

FS 72' crank up tilt over motorized US Tower (self supporting) with
rotator, ready to go!

I have a US Tower TX 472MDP 72' self supporting crank up (motorized)
tilt over tower ready to go.

4 x IV-16 Coax arms
TB 20 s Thrust bearing
TRX80 Raising structure
MD75 Motor
MCL 100 Control switch
MD10 Mast
Mounting Plate

The tower is on the ground in excellent condition and needs only the
anchor bolts and
concrete base.

collapsed size is about 22 feet.
weight is around 1500 lbs

I am in Lynchburg VA

Loss of work forces me to sell this beauty.

I will also throw in the H IVCD-45 Higain Control box and heavy duty
rotator (now mounted on the tower)
and full sized telerex multi-band Beam

If interested,
give me a call and make an offer

Unfortunately, my variable transmission line is Z0 = 388 ohms and I
wouldn't trust my homemade 388 ohm SWR meter for wattmeter accuracy.
The lengths of my T-line sections are also not super accurate.

Let me get straight what you are saying. As I understand it, you are
saying that if you chop off one foot of coax at a time when driving
a fixed amount of forward power into a 3:1 mismatched load, the SWR
will change from, e.g. 3.8:1 to 1.9:1. Is that correct?

I think everyone appreciates the fact that if he/she destroys the efficiency
of his/her transmitter by whatever means, then that is not inconsequential.
But that's not really what the discussion is about, is it? SWR doesn't depend
upon the efficiency of the transmitter, does it?

Hi Richard
Since Cecil's reference to "nobody" implicitly includes me, I beg to be
removed from that group.

How to measure source impedance.
Connect an adjustable load directly to the source, forget the transmission
line.
When the load gets hottest for the least power into the source, their
impedances are matched.

3400. Re: Eznec modeling loading coils?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-17 20:12:00 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vjvocg8ntr4p98@corp.supernews.com>
Source record: 110443

There are a couple of problems with the analogy. First, of course, is that there is no secondary winding to convert the primary's magnetic field to the current I you reference. The "aether" has no N and no I, and doesn't do this. The second problem is that a simple transformer model, or any other lumped-element circuit model, is valid only if its dimensions are very small compared to a wavelength(*). A mobile whip loading coil is often long enough that a current gradient can occur from one end to another, so a single lumped element model might be inadequate.

Roy Lewallen, W7EL

(*) A particular problem with the mobile loading coil in an electrically small whip is that the current changes a great deal over even a very short distance, as it goes from zero at the end of the whip (assuming no top loading) to a large value at the base. It sounds like sort of a circular argument, but a lumped element model loses accuracy any time there can be a current gradient across the component. Interestingly, the problem becomes less and less severe as top loading is increased, because it reduces the current gradient along the whip. You *could* quite accurately model a loading coil as a single lumped element if you had enough top loading.

Hi OM,

You are stricken from that group then. Your conscription is ended and
we still all remain content by universal acclamation. ;-)

Myself I can tolerate up to 10dB without care so 1.62dB is hardly as
monumental as the vivid reactions to this news would evoke. I only
test claims to the level of 1dB to be generous. I would note that

most claims fail to achieve even that value.

Hi Cecil,

Your trepidation about the accuracy is well taken, but perhaps overstated for a first pass approximation. I will leave you to judge that, but I would point out, that if you can conspire to load both ends to mismatch as I have described (or worse), you should see the same symptoms. That your lines do not fall on cardinal points; I have faith in that your craftsmanship is of high enough caliber that it won't make any difference if you can replicate the same wavelength interval (which means you will probably need to work this out above 20 MHz). Error is not inescapable, but your regression analysis should reveal the same trend.

If you in fact do not know the characteristic source Z of your transmitter, then forcing a known value imparts a basic maximum. In other words, what ever unknown value in parallel with a known value could never exceed that known value. A simple 50 Ohm load at the transmitter output guarantees that the source could never exhibit any higher value. This feeding your 388 Ohm line is by far and away more severe than any of the reports or tests I have offered. With the far end terminated in another 50 Ohm load, then you should see extremely wide variation. Your regression analysis should reveal the same pattern as you found with my data (what you call nonlinearity). You may then compare your regressions' chi-squares.

Or simply measure the line loss in your standard configuration and compare it to the severely mismatched arrangement I describe above (both ends terminated in 50 Ohm loads).

Accuracy demands a lot of front work, but a first pass test such as I describe should present a quick resolution to whether or not you want to commit beyond to engage in that labor. The worst of this is how much you can (or your transmitter can) tolerate working into these deliberate mismatches.

That is what I mean, By looking at both ends at the same time with a dual
trace scope. I guess I could also go A - B. I have the stuff to do it with.
About 60 feet of 9913 that I can short the far end on, a dual trace 100 MHz
scope, and MFJ analizer as a signal source. The latter is also usefol for
finding exact 1/4 wavelength frequency, as I can't measure the coax length.
(Goes through several walls).

Hi Tam,

A dual trace scope is not the same as a dual channel scope. You need
the latter. It needs to have a two channel "add" (which is seriously
derated from the usual spec.s). It also needs to exhibit a high CMRR
at the frequency you plan to test at. It also needs to exhibit a high
Common Mode ability (the CMRR may be sufficient, but you can also
drive the front end into saturation if the mode potential is too
high). You also need to show great care to grounding that scope such
that it does not inject even more Common Mode. This then implies that
you need to know what the Common Mode potentials are and you return to
the issue of ground once again, given this cable runs through several
walls.

Far less time would be involved in simply taking a handheld meter with
an RF probe. Connect it, and then remove yourself (physically, that
is do not actually hold the meter) as a source of error.

This is a Usenet newsgroup. Nobody owns it. Nobody moderates it. Anyone
can use it.

Learn to live with it: set up your newsreader to ignore all postings
with subjects beginning "FA" or "FS", and you won't be aware that "this
stuff" even exists.

Richard,
The frequency is going to end up around 4 MHz, which is not too bad for ALT.
We will see what happens. I have a pair of 10X probes, which I can match. I
guess we both know I am going to end up measuring the loss of the coax

The guidelines for this news group is at URL:
http://faqs.jmas.co.jp/FAQs/radio/personal-intro

It sez:
The groups r.r.amateur.antenna, .boatanchors, .dx, .equipment, .homebrew,
and .space are for more specialized areas of ham radio: discussions about
antennas, the older tube based amateur, military, and commercial gear,
commercially-made equipment, homebrewing, and amateur radio space
operations. The .equipment group is NOT the place for buying or selling
equipment; that's what rec.radio.swap is for.

But as far as I know -- this group is unmoderated.
Some Moderated news group can be found at yahoo, but folks complain about
"restricting freedom of Yaking"

So when it is free and the lawless have no fear -- you have the mess that we
have on the news groups.

IGNORE is the key word.

Still lots of good info here however.

Keep the faith.

Let me attempt to answer your questions:

1. I do not know the "Z of a transmitter." For that matter, I am not sure what that expression means, but I take it to mean the internal resistance of the output stage feeding power to the external load.

2. I seriously doubt that anyone knows . . . or cares.

3. There is no need to know, since its value, whatever it might be, plays no role in the design and implementation of the external portion of the system driven by the transmitter.

4. The "internal resistance of the output stage(s)" is not necessarily the required load resistance for the transmitter. The former may be unknown; the latter is a key parameter of the transmitter and supplying that required value is mandatory if the transmitter performance specs are to be obtained. The former doubtlessly has a value, although it may be time-varying and highly dependent upon other knowable and unknowable factors. The latter is a fixed value. I suspect that not even the amplifier designer knows or uses this internal resistance value. What he does know is what load resistance is required at the output terminals to obtain the specified performance of the amplifier.

Several people on this newsgroup keep trying to get this message across, to no avail. So, let me pose a question or two in response:

If you knew "the Z of a transmitter" (which I presume is your terminology for the "internal resistance of the output stage"), what would you do with that information? Where would you use it? What are you prevented from doing or knowing by not having that information?

Fair enough?

Roy, Chipman on page 138 of "Theory and Problems of Transmission Lines"
makes the statement

" The conclusion is somewhat surprising, though inescapable, that a
transmission line can be terminated with a reflection coefficient whose
magnitude is as great as 2.41 without there being any implication that the
power level of the reflected wave is greater than that of the incident wave.
Such a reflection coefficient can exist only on a line whose attention per
wavelength is high, so that even if the reflected wave is in some sense
large at the point of reflection, it remains so for only a small fraction of
a wavelength along the line away from that point . . . The large reflection
coefficients are obtained only when the reactance of the terminal load
impedance is of opposite sign to the reactance component of the
characteristic impedance."

Chipman makes these remarks after his derivation of the operation of lines
with complex characteristic impedance.

3415. Re: 30 meter add-on for HF2-V idea

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-17 23:34:15 UTC
From: t_ashland@yahoo.com
Message-ID: <6e6aeba9.0308171534.77376648@posting.google.com>
Source record: 110459

I finally got around to putting up a 30 meter quarter wave wire in
parallel to the HF2V instead of the 30 MRK kit. I ended up pruning
about 1 foot of wire to get it to about 1.5.1 across the band. I also
had to tweak 40 and 80, and have them where I wanted them. I had an
old HF6V vertical and stole some parts off it to make this 30 meter
add-on. The wire I used was flex weave with stand offs about 4 inches
from the vertical. Seems to work great!
In my junk box, I also found the old parts from the HF6V vertical. I
think I might have all the parts for the 30 MRK. Is there anyone out
there who can give me the diameter of the coil as well as turns and
the capacitance of the capacitor? I looked at Bencher's website, but
I think they make it a little vague to keep people from home-brewing
;-P

Thanks very much for that additional information about the consequences of the magnitude of the reflection coefficient exceeding one. I couldn't find it in any of the electromagnetics or transmission line books on my shelf, which at last count include about 13 texts. Chipman, alas, isn't among them. It confirms what I suspected, and provides further evidence that the posted equation is universally correct.

While I'm mentioning books, I picked up a couple at Powell's Technical Bookstore yesterday evening that look like real winners. They're _Engineering Electromagnetics_ by Nathan Ida (2000), and _Electromagnetic Fields, Energy, and Waves_ by Leonard M. Magid (1972).

The thing that attracted me to Ida was that he explains things in very clear terms, then follows each section with a number of examples showing how the principles are applied to real problems. And answers to all the exercises (separate from the examples) are at the back of the book. This is a pretty recent book and fairly expensive. I was lucky to have found a used copy at a reduced price.

Magid has the most rigorous derivation of power and energy flow on transmission lines I've seen, as well as other extensive transmission line information. One conclusion that pricked my ears was that on a line with a pure standing wave (e.g., a lossless line terminated with an open or short circuit), ". . . power (and therefore, energy) is completely trapped within each [lambda]/4 section of this lossless line, never able to cross the zero-power points and thus constrained forever to rattle to and fro within each quarter-wave section of this line." I had reached this same conclusion some time ago, but realized I hadn't properly evaluated the constant term when integrating power to find the energy. But I didn't want to get into the endless shouting match going on in the newsgroup, and dropped it before going back and fixing my derivation. Hopefully some of the participants in power and energy discussions will read Magid's analysis before resuming. I found this book used at a very modest price.

Message-ID: <20030817211807.06903.00000706@mb-m03.aol.com>
Source record: 110461

Does anyone know anyone who does tower work on Long Island? I need a new cable put on a US Tower tubular tower that sits in a raising/rotating fixture. I can't get the tower out of the boot (in the raising fixture) that supports it , It has to be removed from the support to get the end of the cable.

Does anyone know someone who does tower work?

Also, anyone have a source for stainless stell cable?

Tks,
Gerry

Well Roy, I was trying to remove the inter coil and end to end
capacitance from the equation so a simple analogy could be made. Thus
if there was a current change the cause could be removed from the
itemizerd inductance alone so that other reasons would have to be
researched for energy changes or losses.
(simi;ar to transmission lines and filter circuits)
Still I bend to your superior experience in this matter and withdraw
my comments so that I do not mislead others. My comments emanate from
lumped circuit theorems where the other half of the transformer shows
up at the receiving end as being discussed in another posting
initiated by Dr Slick.
The difference being the environnment, one of specialised steel
laminates and the other being the eather. Looking at things that way
forces one to review
the different coupling to ground effects and other anomolies of this
particular situation

Hi George,

You mean the two I've responded to? The others are quite mute to a
simple question that relates to the topic line. But not so mute that
I haven't noted reams of correspondence in exchanging insults and
huffing in general:
>>I see you're reduced to insults now.
An insight that was drawn upon more than once.
>>If that's all you ever meant
Again, beating that dead horse was preferred.

As for your last question, I have answered it in the post you just
quoted.

>2. I seriously doubt that anyone knows . . . or cares.
One of that party has objected to others thinking for him, or 50% of
the respondents. True, he doesn't care, neither do I and we covered
that ground long ago. Neither of us popped an artery because Mismatch
Uncertainty presented 1.62dB loss.
>-------1.62 db here, 1.62 db there-------;^)
If the subject has such lack of importance, he showed far more
tolerance to its discussion - no insults offered and no dead horses
beaten. ;-)

He's obviously talking about net energy. There is no impedance discontinuity
in a continuous piece of transmission line so there is nothing to cause
reflections at the zero-power points. Net energy doesn't cross the zero-
power points but equal forward energy and reflected energy must cross the
zero-power points. That is easy to prove by observing ghosting on a TV set
being fed by 1000 feet of ladder-line. If energy is completely trapped
within each 1/4WL section, ghosting would be impossible.

I forgot to add. At the "zero-power points", either voltage or current is
zero. All that means is that all the energy is contained in the opposite
field. If the voltage is zero, the H-field is at a maximum. If the current
is zero, the E-field is at a maximum. The energy still exists, just in one
field or the other. V*I*cos(theta) is NET energy. The power in the forward
wave is Vfwd*Ifwd and the power in the reflected wave is Vref*Iref. Those
values are constant all up and down the line for a lossless feedline.

> and /or minimum distortion into a specific load.

Just my point, Ralph... you should worry about your speakers being
within the range of LOAD impedances that the amplifier is designed
for, but you seldom would worry about the SOURCE impedance. You
should worry about the antenna-load you present to your transmitter or
amplifier being within the range of impedances for which the
transmitter or amplifier is designed, but why worry about the
transmitter or amplifier source impedance?

(Some folk worry about audio amp damping factor, but it tends to be
grossly overemphasized...see postings over the years by Dick Pierce in
the audio groups for the simple explanation why it doesn't matter all
that much.)

Cheers,
Tom

Hi Tom,

You only need drive down the road some 25 minutes if you are serious.
Less time than that spent in all these postings that have you worried.
I've driven to Mukilteo 5 days a week for several years and its not
all that far and almost a straight shot especially with you on the
speedway.

When can I expect you? ;-)

In a remote control project, I have a small FM 433.92 MHz sender module which according to its specifications requires a "30-35 cm whip antenna for 200 meter range in open air". However, I'd like to put the antenna INSIDE a plastic box, containing some electronics, which is only 5 times 10 times 20 cm, where 5 cm is the height.

I wonder how should I proceed to maximize the range of the transmission (of digital signals from the box):

- Should I squeeze in an antenna horisontally in the box?
or should I utilize the vertical space available?

- Should the antenna be as long as possible, or a harmonic division of the ideal "30-35 cm"?

- Also, what material should the antenna be made of? And what shape (thin/thick, tube/square, solid/hollow)?

- Can I use a loop antenna?

Basically, I have no restrictions on the recieving antenna, other than distance. How could I design/position it in order to maximize the working range from the transmitter?

(I hope this question is not malplaced in this forum. Any thought on any point above is most welcome!)

> field.

Not quite all. It also means that there is NO power since P = V x I.

There can be lots of energy present but none of it is flowing past
the zero voltage or zero current point; hence no power.

To believe that energy is flowing across a zero voltage or zero current
point requires the rejection of the view that instantaneous power is
equal to instantaneous voltage multiplied by instantaneous current.
Rejection of
P = V x I would have wide impacts on our understanding of electrical
power and energy flows. (My light bulb is not drawing any current but
there could still be energy flowing in it!?)
Think carefully before going there.

Floyd Davidson wrote:
"Unless of course that shuts down ,or even destroys the source devices in the process (adjustable load gets hottest for least power to the source as proposed by H. Adam Stevens)."

H.`s variable load can determine a match because maximum power transfers if the load impedance is the conjugate of the source. But, least power input may not coincide with maximum power output. Low internal source impedance as compared with the load impedance usually is more efficient, but not necessarily so. With impedance produced by switched-off time as in the Class C amplifier, impedance is not only a function of internal loss.

A Class A amplifier has constant power input so that the more power delivered to a load, the less power is dissipated in the amplifier.

Simple determination of source impedance is to divide the open-circuit voltage by the short-circuit current out of the device. That requires a source impedance that is the same at matched loading as with a shorted load. As Floyd notes, the extremes, open and shorts, can shut-down or destroy from too much voltage or current.

Near the region of a conjugate match, less severe voltage and current are likely. Maximum power transfer to the load occurs at the conjugate match point. Heat rise would be the likely cause of damage to a transmitter at maximum output. Power output measurements can be made quickly to limit transmitter and load temperature rise in and around the load impedance which gives maximum power output. A versatile load can be used to determine the conjugate match and thus the source impedance.

The transmitter may not be designed to deliver maximum power output even momentarily and may have built-in protection to prevent it.

Feedback may not increase maximum power output without regard to distortion. In an audio amplifier, the output impedance may be made to look like a short to the speaker and thereby put the brakes on its movement as it tends to ring on after excitation. The same feedback lowers distortion at a given power level, or said another way increases power output for a given level of distortion, but maximum power output without regard to distortion is unaffected by the feedback. R-F amplifier negative feedback likewise has no effect on the all-out maximum power.

Best regards, Richard Harrison, KB5WZI

What's your view on the best HF multi band vertical for me.

I know the fact I am looking at multi band is a compromise with respect to performance but who can afford mono band antennas for all bands ;-)

I am able to mount something on a pole putting the base of the antenna about 10 - 20 ft above ground.

I was thinking about the Cushcraft R6000 but I am open to ideas.

Cheers..

Matched impedances transfer maximum power.
Now add a transmission line of a different impedance between the source and load.
Consider what happens to a reflected wave when it gets back to the source.
If the source is matched to the line, is the reflected wave dissipated as heat in the source?
What if the source's impedance is much lower than the line?
Does it then begin to look like a short to the reflected wave?
When all the impedances are matched the solution is just a simple traveling wave from source to load.
I like that.

Hi OM
I just gave away an R8.
I have the BiggIR vertical.
www.steppir.com
No compromises but you'll need a radials.
Mine's grounded on a very long fence.
It is a "mono band antenna for all bands" => 40 - 2

Roy:

Interesting point and I don't recall reading or hearing it elsewhere.

The following is dashed off without fully thinking it through, so no
warranty on its accuracy.

If you think of a sound wave (longitudinal transmission, of course) in
a lossless acoustic transmission line terminated with a short, the
individual air molecules within each 1/4 wave section are likewise
trapped since at the 1/4 wave points there is zero sound pressure.
This may be a useful analogy for the electromagnetic transverse
propagating T-line.

Not obvious at all.

> There is no impedance discontinuity
> in a continuous piece of transmission line so there is nothing to cause
> reflections at the zero-power points.

A mechanical analogue may help. Consider that executive toy: five steel
balls attached by string to a frame. Pull back the ball on one side and
let it go, when it strikes the second ball, the fifth ball swings up.
Reduce this toy to just two balls.

Pull one back, when it strikes the second, it swings out, then swings
back striking the first which then swings out. It is clear that there
is energy transfer between the balls.

Redo the experiment by pulling both balls back and letting them go at
the same time. After colliding, both balls bounce back. Were you to
place a very thin sheet of steel between the balls at the collision
point it would not move. Since Work is Force x Distance and the Distance
is zero there is no Work being done on the sheet so no energy can be
crossing it.

In the shorted or open transmission line (from Magid, above), the
analogue is two clumps of charge rushing towards each other and meeting
at a voltage maximum (current zero). No charge crosses this point
(obvious because the current is zero), but the charge coming from each
direction builds to a voltage maximum and bounces away again (since
like charge repels).

> Net energy doesn't cross the zero-
> power points but equal forward energy and reflected energy must cross the
> zero-power points.

Not possible since NO energy crosses the zero voltage and zero current points (unless you want to reject Pinst = Vist x Iinst).

> That is easy to prove by observing ghosting on a TV set
> being fed by 1000 feet of ladder-line. If energy is completely trapped
> within each 1/4WL section, ghosting would be impossible.

This ghosting argument appears quite powerful along with the somewhat similar observation that information can be sent in both directions simultaneously on a phone line.

The difficulty I encountered, while trying to understand, is that simultaneously holding the views that:
1) ghosting is caused by reflected energy flowing back along the line; and
2) Pinst = Vinst x Iinst
required too much double think.

Item 2) seemed to be too universally applicable to let go, so a better understanding of 1) was required.

Although it seems unrelated, it is worthwhile to consider how to send information along a line without sending energy in the same direction.

For simplicity, consider an ideal transmission line of useful length with
a matched Thevenin DC source on the left and a matched load connected through a switch on the right. Initially, the switch is open and the line is charged to V: the voltage of the voltage source. Observe that there is no current flowing anywhere, hence no energy flowing and therefore no power. This is entirely consistent with 2), above.

Close the switch. Charge starts flowing from the line through the load. A negative voltage step begins to propagate backwards along the line at the velocity of the line. When this voltage step reaches the source, the line has entered a new energy state with constant voltage V/2 across its length, a current of V/2/R flowing and energy is flowing from the left to the right at V**2/R/4 Watts. This power is dissipated in the load at the right.

Opening the switch will cause a positive voltage step to propagate to the left and when it reaches the source, the line will have been restored to its initial conditions with no energy flowing.

A detector at the source (monitoring voltage or current) can determine if the switch is open or closed (after the voltage steps have finished propagating), thus information can be transferred from right to left while energy only flows from left to right.

This information is transferred by doing something that changes the energy state on the line and waiting for the new energy state to propagate along the line. It is important to note that the propagation of the change in energy state is not the same as the propagation of energy. They can, and often do, occur in different

directions at the same time.

And to return to the original question, this is the cause of ghosting; it is the propagation of the change in energy state on the line that results in ghosting. If the source was matched, then the line settles to its final state in one round trip and no ghosting is observed. When the source is not matched, it takes several round trips for the line to settle and ghosting is what you see.

By the way, this is not quite Magid's situation since he was saying the energy completely bounced back and forth only when the line was open or shorted. In other situations with standing waves, some of the energy is bouncing within the 1/4 wave sections, while other energy is flowing forward.

...Keith

It means there is no NET power transfer. There are power flow vectors
in both directions that are equal in magnitude. Reference: _Fields_
and_Waves_in_Communications_Electronics_ by Ramo, Whinnery, & Van Duzer,
section 6.10, page 350, where they describe Pz-, the reflected wave
Poynting vector and Pz+, the forward wave Poynting vector.

> There can be lots of energy present but none of it is flowing past
> the zero voltage or zero current point; hence no power.

There is a forward power flow vector and a reflected power flow vector.
There is no net power flowing past any point. There are, however, equal
magnitude component constant power flow vectors flowing in both directions.

> To believe that energy is flowing across a zero voltage or zero current
> point requires the rejection of the view that instantaneous power is
> equal to instantaneous voltage multiplied by instantaneous current.

No, it doesn't. It only requires acceptance of Ramo, Whinnery, & Van Duzer.

However, to reject energy flow across a zero voltage or zero current
point requires a confusion of cause and effect. Energy flow in both
directions is the *CAUSE* of the standing waves. You simply cannot
turn around and say that standing waves eliminate their own cause
but continue to exist anyway.

> Rejection of
> P = V x I would have wide impacts on our understanding of electrical
> power and energy flows.

Nobody is rejecting it. If the lossless stub is one second long, it takes
two seconds of *POWER* to bring it to steady-state. If the stub contains
no moving energy, where did all those joules go? They cannot disappear or
stand still. If they are moving, power exists.

H. Adam Stevens wrote:
"Until one breaker goes and the rest of the grid can`t handle the load."

I was in England last week and missed the blackout. It would not have affected the Houston Texas area served by Houston Lighting & Power Company had the anomaly originated outside Texas. HL&P, or whatever the company calls itself today, refuses inmterconnection with Gulf States Utility Company or with any company with interstate business. To interconnect would place HL&P under the control of the Federal Energy Regulatory Commission (FERC) which controls interstate energy and power commerce.

Protective relaying is imperfect. It may be much cheaper to improve data machines and software used to adapt power grids to anomalies than to invest countless billions to cver-build facilites for the rare anomaly which spreads.

Making FERC less onerous might get heavyweights like HL&P to engage in interstate commerce and be there to pick up the load that others can`t handle in emergencies. I believe the least practical regulation is the best regulation, but de-regulation of power companies has proved stupid. Complete de-regulation of natural monopolies must be done with great care. It makes no sense to allow middle-men to resell a service and add little save expense themselves.

Best regards, Richard Harrison, KB5WZI

Do not be afraid to admit that you have changed the definition of P = V
x I
and therefore do not accept the standard definition.

When I learned Pinst = Vinst x Iinst there were no caveats about how
Pinst meant Pnet. Instantaneous energy is flowing or it is not. When
Pinst
is 0 for all time, then there is no energy flowing.

To satisfy your theory (and minimize double think), you have had to
change
this to Pnet is zero to allow these cancelling powers to flow. So be it.

> There is a forward power flow vector and a reflected power flow vector.
> There is no net power flowing past any point.

True, sort of. At the quarter wave points where voltage or current are
always
zero, there is no energy flowing. Period.

At other points, energy flows in one direction for a quarter cycle and
then in the other direction for the next quarter cycle, producing a net
of zero. A true instantenouse power meter (one which measures V and I
and
displays V x I) will easily demonstrate this. As a thought experiment,

move such a true power meter along a shorted or open line and think if its indications in the time domain, then do the averages. It will be quite instructive. Repeat for a line terminated in other than its characteristic impedance.

By the way, since energy flows forward for a quarter cycle and backwards for the next, the maximum distance travelled by this energy is one quarter
wavelength on the line. It is not flowing all the way to the end of the line and then back. There is not enough time for this to happen (on a multi-wavelength line) since it changes direction every quarter cycle.

> turn around and say that standing waves eliminate their own cause
> but continue to exist anyway.

Not quite. Standing voltage and current waves (which are not waves in the normal sense) can be observed on the line. They can be measured with real voltage and current instruments; as can real energy flows with a real (V x I) power meter (but not a 'Bird watt' meter which is doing something quite different). It happens that if you assume the existence of forward and reverse voltage and current waves, mathematical functions can be derived that will produce the same distribution of voltage and current as observed on the line. This is extraordinarily convenient some analysis but does not mean that these assumed waves are real.

A mechanical analogue would be to look at a guy wire on a pole. You can analyze the forces as two vectors at 90 degrees (or any other angle of convenience!), but never make the mistake of assuming that there are actually two guy wires present. Just because it is mathematically convenient to assume the existence of two vectors does not mean they exist.

> > Rejection of

>
> Nobody is rejecting it. If the lossless stub is one second long, it takes
> two seconds of *POWER* to bring it to steady-state. If the stub contains
> no moving energy, where did all those joules go?

This energy is indeed stored in the stub. None of it moves across zero voltage
or current boundaries. Between these boundaries, it is indeed moving as it changes from being stored in the capacitance and inductance of the line.
This time variation of the location of the stored energy produces the observed
voltages and currents on the line.

> They cannot disappear

Absolutely. They do not disappear.

>or stand still.

With AC excitation they do not stand still, but when similar analysis is done
for a line excited with a DC source, the energy does indeed stand still. An
open line stores the energy in the capacitance and a shorted line stores it
in the inductance.

> If they are moving, power exists.

Yes, but it never moves more than a quarter wavelength.

> involved ?
>
> Reg, G4FGQ

Yes, on page 201-202 of Pozar's "Microwave engineering".

[s11]**2 + [s21]**2 = 1

For a lossless passive two port network, where the brackets
indicate magnitude only.

"If a network is lossless, then no real power can be delivered to
the network." This in essence is a conservation of energy principle,
where in a lossless passive network, if you have -3dB insertion loss,
you must have -3dB return loss as well (half the power through, half
reflected, none dissipated).
This would give you: (0.707)**2 + (.707)**2 = 1

When ever [s11]**2 + [s21]**2 does NOT equal 1, then the network
has losses.

Therefore, the reflected voltage can never be greater than the
input voltage for a passive network, and the reflection coefficient
can never be greater than 1 for such a case.

From Pozar's Microwave Engineering (Pg. 606):

Reflection Coefficient looking into load = (Zl-Zo)/(Zl+Zo)

Where Zl is the load impedance, and Zo is the characteristic
impedance reference.

The reflection coefficient cannot be greater than unit.

How can you have an S21 that is greater than unity with a passive
network?

My vote would have to be the Gap Titan 10-80m. no radials needed. I didn't think it would do very good compared to my full wave loop at 38ft. But I will tell you it does excellent. As soon as I got it up in the air we worked PZ5 and YS1 with 100 watts with 59 signal. Switched to my loop with the YS1 and went 56.

Yes there is energy flowing, and it is flowing in both directions if it
is flowing in one direction. Otherwise there would be no standing wave.

The waves flow right through each other so long as the impedance is
uniform. Energy flow is unabated at those points of illusory zeros.
Those zeros are not zeros at all in the forward and reverse waves. They
only appear as zeros when your sensor can`t separate the forward from
the reverse. Get a proper directional sensor and the forward wave is
sensed as full amplitude as is the reverse wave.

Hi All,

from:
http://physics.nist.gov/cuu/Units/units.html

newton N m ï¿½ kg ï¿½ s^-2

volt V m^2 ï¿½ kg ï¿½ s^-3 ï¿½ A^-1

farad F m^-2 ï¿½ kg^-1 ï¿½ s^4 ï¿½ A^2

henry H m^2 ï¿½ kg ï¿½ s^-2 ï¿½ A^-2

ohm omega m^2 ï¿½ kg ï¿½ s^-3 ï¿½ A^-2

permittivity e0 farad per meter F/m

permeability ï¿½0 henry per meter H/m

for e0 (electric constant) from:
http://physics.nist.gov/cgi-bin/cuu/Value?ep0|search_for=universal_in!
8.854187817 ï¿½ 10^-12 ï¿½ F ï¿½ m^-1

for ï¿½0 (magnetic constant) from:
http://physics.nist.gov/cgi-bin/cuu/Value?mu0|search_for=universal_in!
12.566370614 ï¿½ 10^-7 ï¿½ N ï¿½ A^-2

Zc = (ï¿½0 / e0)^0.5

solving:

Zc = 376.730 ï¿½ ((N ï¿½ A^-2) / (F ï¿½ m^-1))^.5

expressed as products:

Zc = 376.730 ï¿½ (N ï¿½ A^-2 ï¿½ F^-1 ï¿½ m)^.5

substituting terms N and F:

Zc
=
376.730
ï¿½
((m ï¿½ kg ï¿½ s^-2 ï¿½ A^-2)

ï¿½
(m^2 ï¿½ kg ï¿½ s^-4 ï¿½ A^-2 * m))^.5

combining terms:

Zc = 376.730 ï¿½ (m^4 ï¿½ kg^2 ï¿½ s^-6 ï¿½ A^-4)^.5

root of terms:

Zc = 376.730 ï¿½ m^2 ï¿½ kg ï¿½ s^-3 ï¿½ A^-2

Which, if no one has noticed, is the same units for measuring the Ohm.

Zc = 376.730 ï¿½ ohms

That is, the Z of free space is expressed in exactly the same terms as a carbon composition resistor. Now given the genesis of this debate is that free space Z is somehow different from the expression of Radiation Resistance (e.g. 37 Ohms for a monopole) the only possible rhetorical objection is that free space is not lossy like a carbon resistor (non-dissipative). Well, neither is the Radiation Resistance! Even rhetoric fails. ;-)

An antenna is a structure that transforms Radiation Resistance into the Impedance of free space, as shown, and by definition. Both use identical MKS units, both are identical characteristics.

If someone has another method of deriving the Z of free space, they may well rest assured that it will eventually collapse to the same expression cited above. Offer your example for a similar tour through the fascinating world of Physics.

You can still call it a transducer though - or a thigamajig.

A reflection coefficient implies that transmission lines long in terms of wavelength may qualify as passive networks.

At the open-circuit end of a long transmission line, current is interrupted by the open circuit. Having nowhere else to go, energy in the current wave must be accepted by the voltage wave which doubles on the spot. 2X the incident voltage is the sum of the voltage in the incident wave and the voltage in the new reflected wave as they are in-phase. The reflected voltage is no greater than the incident voltage. It is equal to the incident voltage. It`s the sum that doubles.

Does anyone have access to Proc. I.R.E., 39, 767 (1951) by A.M. Clogston describing reduction of skin effect by a new method of laminated wire construction? Should make interesting reading.

Unfortunately, the analogy is not a good one. In a transmission line,
there must exist a discontinuity to cause a reversal of momentum of
the waves. No such discontinuity exists so there is nothing to reverse
the momentum of the forward and reflected waves.

> Not possible since NO energy crosses the zero voltage and zero current
> points (unless you want to reject Pinst = Vist x Iinst).

Ramo, Whinnery, and Van Duzer disagree. They say that the power
reflection coefficient is equal to the reflected Poynting vector
divided by the forward Poynting vector which in this case would
be unity.

> The difficulty I encountered, while trying to understand, is that
> simultaneously holding the views that:
> 1) ghosting is caused by reflected energy flowing back along the line;
> and 2) Pinst = Vinst x Iinst required too much double think.

Life is tough all over. :-) What I am saying doesn't require double
think. :-)

> Although it seems unrelated, it is worthwhile to consider how to send
> information along a line without sending energy in the same direction.

Information transfer doesn't require energy? Methinks you are confusing
the carriers of the wave with the waves themselves. Zero carriers may
indeed cross the zero power point, but that does not prevent energy
from crossing the boundary. It just means that the energy crossing the
boundary must be equal in both directions.

One point. The power is not Vavg * Iavg. The power is Vavg*Iave*cos(theta)
All up and down a shorted lossless transmission line, theta is equal to
90 degrees. Around a voltage zero point, on one side the voltage is equal
to 0.00000001 volts and is 90 degrees out of phase with the current, i.e.
zero power. On the other side of the voltage zero point, the voltage is
equal to -0.00000001 volts and is 90 degrees out of phase with the current.
There are an infinite number of points where the voltage is 90 degrees out
of phase with the current. That's why the average power is always zero, not
because the average voltage is zero, but because the voltage is *ALWAYS* 90

degrees out of phase with the current in a lossless shorted feedline.

> When the source is not matched, it takes several round trips for the
> line to settle and ghosting is what you see.

Put an amplifier between the TV set and the feedline. Let the amplifier have as high an impedance as possible (insulated gate FET). That will cause reflections. Those reflections will still be there during steady-state and observing the ghosting will prove that, during steady-state, the ghosts have made one or more round trips back to the source where they are re-reflected (assuming a mismatched source or a Z0-match provided by a network).

Incidentally, the argument that Thomas Edison used to prove that
power distribution systems would never be AC is that they would
burn themselves up trying to provide maximum power transfer. He
never conceived that they would be more interested in efficiency
than maximum power transfer. :-) So why can't we have a 95%
efficient RF power amplifier?

Hi Tom,

Yes, I have noticed the 30 cent jump in the cost of gas. ;-)

How about lunch at Lake Stevens then? I drove that for a couple of years too, back when your outfit was called HP. I worked in Larry Whatley and Nick Pendergas's group during the Marysville to L.S. move (to set a time frame). 1,000,000 lines of Pascal FFT code in that project. It was fun and I still have a lot of drawings of waveforms generated.

For those who are interested in the nuances of FFT's (and why their own implementation transforms lack resolution or dynamic range); my tenure provided me with a wealth of insight that is commonly unimplemented in current discussions here and generally in trade publications.

Sorry, that's a demonstrably absurd assertion. Tam pointed a good example out a couple of days ago. Here's another -- The product of resistance and capacitance is time. Do we "transform" time by running a current through an RC circuit? There are countless other examples of different quantities having the same units -- it's not hard to find them.

1951? New method?

Sorry I don't have that paper. I came across the phenomenon quite by accident while developing delay line compensation networks at Tektronix about a dozen years ago, when I saw that Copperweld wire had noticeably less "dribble-up", as we called the characteristic shape of a step affected by skin effect, than solid copper wire. I concluded at that time that, although interesting and potentially very useful, it would require a range of conductivities that wouldn't be practical to manufacture -- which might be why I've never seen wire made in a way to intentionally reduce skin effect. The general scheme is to make the low frequency resistance higher, to match the high frequency resistance, by reducing the conductivity as you go deeper into the wire. I imagine what Clogston did was to rigorously derive what conductivity function would be required with respect to depth. Perhaps it would be practical to do over a narrower frequency range than I required (DC to 2 GHz in one case, DC to 10 in the other).

I'd be interested in seeing the paper also.

It can be convenient to define a reference impedance for S-paramters which is not the characteristic impedance of all the pieces of transmission line in the system, and keep the same reference impedance for all your work. For example, 50 ohms is commonly used, even though the system contains sections of microstrip of various impedances. But that's just a convenience for system analysis and design. If you want to try to assign even a little physical significance to reflection coefficient as used on a piece of line, you really should be using the line's characteristic impedance as the reference impedance. In addition, you should realize that it's going to make sense only in a linear, time-invariant system with steady-state excitation, with only one source of excitation (at a time). In addition, it is of course a function of frequency, just as the line's characteristic impedance is.

As others have noted, the magnitude of the reflection coefficient can be greater than unity with a passive line and load. Don't try to read too much physical significance into that, however.

Although the classic definition of (V)SWR involves knowing a voltage maximum and a voltage minimum on a line, I much prefer a definition in terms of forward and reverse voltages. That allows me to think about SWR at a point on a uniform line, and realize that it will be different at different points (because of line attenuation). In fact, the _definition_ I use for reflection coefficient is Er/Ef, or equivalently the ratio of electric fields (or magnetic fields) associated with forward and reverse waves (which then applies also to non-TEM waveguides). From that definition, it's straightforward to determine that rho = (Zl-Zo)/(Zl+Zo). And in keeping with the idea that you cannot have a voltage magnitude minimum less than zero, and because I believe it's more practical than the classic definition to have an SWR definition I can apply to any point on a line, my working SWR defintion is SWR = (|Ef|+|Er|)/(|(|Ef|-|Er|)|). This will align well with the usual formula that SWR = (1+|rho|)/(1-|rho|) when |rho|<=1, but it never gives you a negative SWR. If you can accept my definition of SWR, we can talk about SWR. If you can't, then I just won't talk with you about SWR, and limit the discussion to reflection coefficient which we presumably would be able to agree on.

Cheers,
Tom

Well, I was taking 'x' as a multiplication sign. Did you mean it as
a cross product sign? In any case, your Vinst is *NET* voltage and
your Iinst is *NET* current. We know that the feedline Z0 forces
Vfwd*Ifwd to be a constant value for a lossless line. We know that
the feedline Z0 forces Vref*Iref to be a constant value for a lossless
line. Vfwd+Vref is the *NET* voltage. Ifwd+Iref is the *NET* current.
Of course, their product, in any form, is going to be *NET* power.

> When I learned Pinst = Vinst x Iinst there were no caveats about how
> Pinst meant Pnet. Instantaneous energy is flowing or it is not. When
> Pinst is 0 for all time, then there is no energy flowing.

But RF energy cannot stand still so if it exists, it must necessarily
flow. If there is no energy flowing, then there is no RF. If there is
no RF, then your statements are irrelevant to this newsgroup. :-)

> To satisfy your theory (and minimize double think), you have had to
> change this to Pnet is zero to allow these cancelling powers to flow.
> So be it.

Your Vinst is *NET* voltage equal to Vfwd+Vref. Your Iinst is *NET*
current equal to Ifwd+Iref. Of course, their product will be *NET*
power. It cannot be anything else.

> True, sort of.

Ramo, Whinnery, and Van Duzer will be impressed that you "sort of"
agree with them. :-)

> It is not flowing all the way to the end of the
> line and then back. There is not enough time for this to happen (on a
> multi-wavelength line) since it changes direction every quarter cycle.

Just as I suspected, you are confusing the carriers of the energy with
the energy itself in the waves which moves at the speed of light. A
quarter cycle of time is very, very large compared to the speed of light.

Since water molecules cannot travel at the speed of sound in the ocean,
I assume you would argue that the energy in a tsunami wave cannot travel
at 500 mph, right?

> Not quite. Standing voltage and current waves (which are not waves in

>>no moving energy, where did all those joules go?
>
> This energy is indeed stored in the stub. None of it moves across zero
> voltage or current boundaries.

What exactly, keeps energy from crossing the boundary? Here is an example.

source-------------50 ohm coax--------------+----1/4WL stub-----open

What mechanism of physics keeps energy from crossing the '+' point? Note
that there is no physical impedance discontinuity at point '+'.

This is what I (and Ayn Rand) call "primacy of consciousness" type thinking.
If you believe it strongly enough, your math model will dictate reality.
Something about being able to move mountains with the faith of a grain of
mustard seed. Something about being able to change the SWR by changing the
normalization of a Smith Chart on a sheet of paper. OTOH, I believe in
"primacy of existence", where reality dictates my math models. They may
be wrong but are as close to reality as I can get.

All you have to do to convince me that you are right is explain exactly
how standing waves can be sustained without a forward wave and a reflected
wave (in a system with a single source, single feedline, and single load).

> How do you know that?

I multiplied v(t) and i(t) in the forward and reverse waves and added them as a function of position to get the instantaneous power at each point along the line. Then I integrated to find the energy. As I mentioned in the part of the posting you excluded from your quote, I discovered that I hadn't evaluated the constant of integration. Somewhere along the line, I got sidetracked, and didn't want to get sucked into the interminable argument going on (which I see I've started up again -- my sincere apology to all), so didn't go back and clean it up. I had, however, reached the same conclusion as Magid, so apparently the constant was zero, or didn't impact the results. Magid follows the same process, although I haven't yet followed it through completely.

You've now heard of Magid, and you can very likely find a used copy on the Internet for the price of a couple of bottles of mediocre Pinot Noir in much less time than it would take to drink it (unless perhaps you're a speed drinker). You could get your hands on one with even less effort than I've taken -- I had to walk a few blocks, while you can do it all from your easy chair, only having to rise and face the Sun when the postman comes with your book.

Shoot, you can even get it from the same store where I got mine, if they have another copy just now. http://www.powellsbooks.com.

What must be realized is that the s-parameter reflection coefficients
are *PHYSICAL* reflection coefficients while 'rho' is not a physical
reflection coefficient. s11 and 'rho' do not usually have the same
value. There are physical constraints on s11. The s11 physical
constraints do not apply to 'rho'. s11 is the square root of the
ratio of Pref to Pfwd under special conditions. 'rho' is the square
root of the ratio of Pref to Pfwd under all conditions. There's a
big difference. s11 does not usually equal 'rho' anywhere except
at a one-port load.

Please realize that the s-parameter coefficients are only one
of a long list of possible coefficients. For instance, in a two-
port system with reflections, s11 is usually not equal to
sqrt(Pref/Pfwd). Please define the specific coefficient about
which you guys are arguing.

Well, you can find archived postings from me from 10 years ago that I think demonstrate that I understood how SWR meters actually work back then. And you could probably find my name on a patent that would give you a clue that I was at least starting to learn a little something about transmission lines in 1969 or so, though I readily admit to not worrying about "reflection coefficient" back then. Just hacked through the raw, unabridged transmission line equations. I suppose Reg would think that a better way to learn the stuff anyway. I had bought the King, Mimno and Wing book back then, but didn't get around to actually reading it till much, much later.

Cheers,
Tom

Hi Roy,

>>although the feedpoint impedance is an impedance with the units of ohms,
>>and the impedance of a plane wave in free space also has the units of ohms,
>>they're not the same thing.

So, how do the "ohms" of free space differ from the "ohms" of a
quarter wave monopole's Radiation Resistance?

The demonstrables you offer do not enlighten us in what physical
constants these unique terms of your usage diverge from those in the
MKS system. As I pointed out in my posting, whatever derivation for
the characteristic Z of free space is, it must ultimately devolve to
the identical expression for the common Ohm.

I would offer by way of caution that the expression
Zc = (ï¿½0 / e0)^0.5
where ï¿½0 is expressed in Henrys per meter and
where e0 is expressed in Farads per meter;
that that, too, arrives at the same Ohms employed by carbon resistors
and Radiation Resistance.

This is much like trying to compare miles per gallon and kilometers
per liter. When push comes to shove, the reduction to MKS will reveal
that the same container of gas will get you down the same stretch of
asphalt the same distance no matter what mix of terms you substitute
for liquid volume and length. This goes to include offbeat
descriptive terms like miles per liter; kilometers per gallon; or
furlongs per hogshead for that identical container of gas. Solutions
of proportionality are not unique physical constants.

Unfortunately, the reflection coefficient is also defined as:
Sqrt(Pref/Pfwd) which is usually only equal to your equation
in a one-port network. For a two-port network, those two
values of reflection coefficient are not usually equal. Better
define things better. For a two-port network, Z1 is NOT the
physical Z1. It is the apparent (virtual) Z1 calculated from
the total voltage to total current ratio which is often
different from the physical Z1 above.

Yep, by assuming something that is true only by definition. :-)
If the source is hidden in a black box and includes a circulator
with load, the reflected wave *IS* dissipated as heat in the
source. For some phases of reflected energy, the dissipation does
increase. You say it is because of the mismatch but the mismatch
is because of the reflected waves. So which came first, the mismatch
or the reflected waves? I suggest that the mismatch will not happen
until the reflected waves arrive. Try it with a one second long
transmission line.

Unfortunately, every author and guru that I have ever encountered,
at some point, confuses cause and effect. I'm sorry I can't get over
to the Texas A&M library right now but Magid seems to believe that
standing waves can be sustained without a forward wave and a reflected
wave. Does he explain how that is possible? In all honesty, it is an easy
mistake to make. Even Ramo, Whinnery, and Van Duzer make the same
mistake. Not exactly a quote but: The reflection coefficient is caused
by the ratio of the reflected power to the forward power. Therefore,
the ratio of the reflected power to the forward power is caused by
the reflection coefficient. "Logic" like this seems to abound in
the field of transmission lines.

As I and several others have recently said several times, the "ohms" of free space represent a ratio of E field to H field of a plane wave or, more fundamentally, the square root of the ratio of the medium's permeability to its permittivity. The "ohms" of a quarter wave monopole's radiation resistance represent the ratio of a voltage to a current. An E field is not a voltage, and an H field is not a current. They are different forms of energy, related by Maxwell's equations.

Message-ID: <3f41343e$1_1@mk-nntp-2.news.uk.tiscali.com>
Source record: 110373

Hi folks

Although licensed for over 12 years as a G7... converting 3 years ago to a M0...callsign (with 12 wpm cw), personal circumstances have not until now permitted me to get started on HF.

Problem now is antennas (and indirectly xyl).

Have garden to rear of property, narrow but 80' long from house to boundary. A further 25' is available along side of property, rear to front, but approx 6' proximity to house wall.
Height of proposed feedpoint approx 17' 6" ; height at boundary 12'

Would initially like to cover 14 - 7 and 3.5 MHz with a coax fed horizontal wire dipole of approx 66', and if carefully cut would theoretically get full - 1/2 and 1/4 wave respectively for these bands. An MFJ-949E Atu is available. No garden or roof space for any vertical metal!

That's the idea, but I would welcome constructive comment, especially in the area of feedpoint impedances and swr.

My thanks in anticipation. . . .
Jim

Regrettably, due to shared facilities, I am unable to accept incoming email, so posts to newsgroup pse.

Hi Roy,

Physical constants do not betray physical measurements. The "ohms"
are identical in practice and theory. They are demonstrable in the
Standards laboratory. NIST describes all this at the links offered
and they do not equivocate nor banter terms casually. For any
Professional Engineer, they carry the force of law as the only
authoritative source for definition. I don't expect that standard to
be observed in this forum, as this is just hobby stuff and lord knows
the number of dictionaries that are already hauled off the shelf to
engage debate.

But this is repetition and evidence has been offered. As you have
revealed no new information that changes these relationships, nor have
you revealed any other representation of free space characteristic Z
in terms not already part of the MKS/SI Canon, then I am satisfied
that I will not change your mind.

Source record: 110378

I am proposing putting up a flat top 75 meter dipole at a height of 48'. I would like to use the antenna primarily on both the 75 and 40 meter bands but not always. The antenna will have to be located almost 300 feet from the shack so I intend to use home brew 500 ohm line made with #12 solid copper conductors. The SWR on such a line will be quite high on both 75 and 40 and be all over the map on other bands. How about 160? My question is, what kind of transmission line losses will be present with SWR's up to 10 to 1 or even greater? I have my trusty Johnson Viking Kilowatt Matchbox to do the tuning in the shack.
My present antenna is a 60' flat top dipole over the shack at an average height of 34'. There is approx. 70' of 450 ohm feed line going to the tuner. The Match Box loads the antenna on all bands from 75 thru 10 meters with excellent results and good feed line balance. I had to modify the Match Box to get it to 75 by utilizing the entire link and adding series tuning to it. Eznec reports an swr of over 100 to 1 on such an antenna on 75 but it gets out well. The #18 conductors have got to have hot spots with my 200 watts of output power! So far I haven't set anything on fire!

Comments Please, Mike K6JSY

Source record: 110381

Take an ordinary round solid conductor. For well known reasons at alternating currents it will have a higher resistance per unit length that at DC.

Now, if a round hole is drilled down the centre of the conductor, ie., its highly-conductive center is removed, the AC resistance will be REDUCED. There are, of course, better ways of producing tubes.

The effect is at a maximum when the wall thickness of the tube is about 1.6 times skin depth in the material, ie., when an appreciable fraction of the current flows on the internal surface. The reduction in resistance is only a few percent and for a conductor of given dimensions it affects only the lower frequencies.

It has something to do with internal inductance and the relative phases of the inside and outside surface currents.

It is likely the effect is considered only when transmission line efficiency is of overriding importance, perhaps at power frequencies, the 'hole' in the conductor's center being occupied by a steel tensile strength member.

My one and only reference book is Robert Chipman's "Theory and Problems of Transmission Lines", 1968, McGraw Hill, where the effect is described in a little more graphical detail than above. But the likelihood of obtaining a copy of this book is remote

3488. HB9CV doesn't tune up

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-18 23:26:15 UTC
From: Gary Morton <gary@alma.demon.co.uk>
Message-ID: <rgd0b.918$tv1.8352796@news-text.cableinet.net>
Source record: 110382

At the recent FRARS radio rally I bough a cheap HB9CV antenna for 6m (there were no 3 element yagis on sale). When I got it home I noticed that a hole had worn in the plastic and that some bolts and spacers (for the gamma match elements - if that is the right description) had fallen out. My only concern was for the spacers to hold the "thin rods" away from the main elements. The supplier wasn't particularly helpful. I have a suspicion that the spacing may be critical, but the supplier didn't seem knowledgeable.

The construction didn't strike me as being particularly good and it certainly had a workshop/homebrew feel about it, particularly since some pencil marks still were left on the boom near the holes. But it was fairly cheap.

I found some spacers which made the thin tubes parallel with the elements, although the gaps were not quite the same. It was not possible to adjust the gaps. When raised around 4m from the ground the SWR was about 1.5:1 with the beehive trimmer cap screwed all the way in.

I am interested in how I can tweak the antenna to get a better SWR reading. Am I right in thinking that the gaps between the thin rods (name please!) and the elements is important and if so what is the effect of too big, or too small, or an asymmetric gap?

Also I was told that this antenna was about the same gain as a 3 element yagi, possibly a little better. Was this just sales talk?

Regardless it does seem to work and I had my first QSOs using this antenna. Since I am a QRP operator I would like to get the best out of the antenna possible.

regards...

Message-ID: <Qrd0b.3843$Nc.2566622@news1.news.adelphia.net>
Source record: 110383

Hmmm. A dipole *does* have gain over an isotropic radiator in some directions, but not in others. That is by definition.

I think you guys are confusing "gain in any direction" with "gain in all directions". If you put 100 watts into a 100% efficient antenna, you will put 100 watts into the air. If you put it in all directions (isotropic), it's 100 watts. If you put it into a dipole, it's 100 watts. A dipole has a non-isotropic pattern, which means that some directions in 3D space get less signal than others.

I like passionate discussions about antennas, but it helps to have some facts. It seems like Mike is wrong here.

All the best, and 73,
Dave

Have you considered homebrew?

I have about 30 ft of tubing on a twenty ft mast with
6 30 feet long radials and I feed it with twin lead (actually
600 ohm ladder line) and it works great.

Much cheaper then commercial and I would bet it
works much better. I have worked dx on all hf bands
except 160 with it.

But....radials and transmatch are required.

Source record: 110386

Assuming a VSWR of 10 to 1, reasonable for 80 meters, and assuming line losses are negligible for open wire tuned feeders, also reasonable for a first approximation, your line losses will be about -3 dB.

EZNEC indicates that you will also have a VSWR of about 10:1 on 40 meters.

Conclusion: you will experience about -3 dB loss [1/2 S unit] on both 75 and 40 when fed with 500 ohm line.

Unless you already have the wire and the tools you will be better off going
to Radio Shack and buy one premade. I have the wire, tools, and knowledge
to calculate the roper length. I buy mine ad Radio Shack for less than
$5.00.

You might expect matched line loss of around 0.1dB for 300ft of that type of line in dry conditions. The additional loss due to a VSWR of 10 would be around 0.4dB. The additional loss due to VSWR is probably quite manageable in this case up to about 25:1 where it would be 1dB. Some will argue, you could stand an S-point or two... you choose.

There will be losses in the tuner additional to the above, so factor those into your loss budget.

You have implied VSWR=100 on the 450 ohm line that you are using, or are you quoting the VSWR that would occur on a 50 ohm line?

3498. Load matching puzzle

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-19 01:41:07 UTC
From: k7itm@aol.com
Message-ID: <3200347.0308181741.3691b6b5@posting.google.com>
Source record: 110392

(Food for thought for the relatively new folk here...and perhaps even some old-timers.)

Consider a system (linear, time-invariant, steady-state excitation and all that jazz) in which a source delivers 1 watt to a load composed of a uniform transmission line terminated in a load. Further, this line has some loss and the frequency is low enough that its characteristic impedance is noticably reactive, just as Reg has pointed out. Call it Ro-jXo. What should the impedance of the load be to maximize power dissipated in the load? Is the answer a function of anything else not yet stated?

Cheers,
Tom

Yep, sorry, brain fart. Should have been a '/' instead of a '*'.
The point was (is) that (Vfwd + Vref) can be zero but in a feedline
with reflections Vfwd and Vref cannot be zero. Same for the component
currents.

Nope, the SWR will not be "quite high" on 75 and 40 or anything higher in
frequency. It will be "quite high" on 160. I use such an antenna for the
HF bands and the SWR on the 450 ohm ladder-line never goes higher than
15:1 which is acceptable because 450/15 = 30 ohms. Take a look at my
all-HF-band dipole on my web page.

You assume line losses are negligible and then say line losses will be
about -3dB? Exactly where are those losses occurring?

[s11]=rho, rho being just the magnitude of the s11.

Right, but we aren't talking about the sum of the voltages, but
the calculated RMS voltage of forward and reflected waves, which are
separated by the directivity of your SWR meter.

"Therefore, the reflected voltage can never be greater than the
input
voltage for a passive network, and the reflection coeficient can never
be greater than 1 for such a case."

Please show us a set-up that will measure otherwise.

Zo doesn't have to be the coax impedance. It can be any impedance
you want. What about interstage-matching networks between FETs? Do
you think there are no reflections there? Should you attempt to match
impedances there? I would think so.

let me rephrase:

PA--+SWR meter1+--50ohm line--+SWR meter2+--50ohm line--+50 ohm
(same Z as PA) (50 Ohms) dummy
load
1 2 3

If you measure the SWR at point 1, you let Z1 (Zload) be 50 ohms,
and Zo is the output impedance of the PA. SWR meter1 should be
characterized to Zo.

I've agreed that SWR meter2s SWR reading (at point 3) will not
change as you change PAs impedance, but the SWR at point 1 definitely
WILL.

So, Does the SWR change as you change the source impedance? IT
DEPENDS ON WHERE YOU MEASURE IT! Right at the output of the source,
it will!

From Pozar's Microwave Engineering (Pg. 606):

Reflection Coefficient looking into load = (Zl-Zo)/(Zl+Zo)

It should be easy to see from this well known equation that a
perfect 50 Ohm Zl will definitely change SWR as you change Zo away
from 50 ohms.

Ohms are still always Ohms, regardless of what you are measuring.
And it's very interesting that the E and H fields have units of
Volts/meter and Ampere(turn)/meter, which when you divide one by the
other, you get basically Volts/ampere, just like you would in a
transmission line.

But I don't claim that a wave traveling in a transmission line is
the same as a wave traveling through free space, even if Roy claims
this is what i mean.

==========

Tom, agreed.

The ONLY way of learning about transmission lines is to begin, as you describe it, with "unabridged transmission line equations" at power and audio frequencies. Otherwise the modern engineer's education is sadly neglected and he ends-up on this newsgroup as a severely handicapped bafflegabber convinced he can't possibly be wrong when he misapplies microwave simplifications, all that he is familiar with, to HF and below.

Forgive me for mentioning again that very useful tool in its hey-day, the Smith Chart, still often extolled for its educational virtues, can be misleading to the user who is without knowledge of the behaviour of lines below 1 or 2 MHz. To use what's printed on a Smith Chart in support of an argument convinces only the person feeling in need of support. It's about as convincing as making reference to an author who nobody beyond the referrer has ever heard of and is never likely to get his hands on. I am not an ignoramous but I must confess I have never used a Smith Chart in anger in my 55 years of experience of one sort or another. Never felt in need of it! Neither have I ever met anybody else who has either.

It should not be forgotten this newsgroup is primarily intended for exchange of information between radio amateurs. It is fairly clear there's a number of retired professional engineers who are also radio amateurs who frequent this newsgroup. Fine! I'm a long-retired engineer myself. There are also a sprinkling of engineers who are professionals in that they are paid for their services of some sort or another. There are some people, perhaps with some small historical justification, have the audacity to consider themselves to form an informal Establishment. Foundations of Establishments lie on shifting sands.

But whatever messages pass between these many-varied people, all with quite legitimate interests, it is suggested they are adressed in plain-English terms as understood by ordinary people. Radio amateurs are ordinary people.

To return to Reflection Coefficient, although of academic interest since Oliver Heaviside, it first became of practical interest to telephone engineers in the early 1910's after the invention of the thermionic valve amplifier. It was used immediately after its invention not only in radio transmitters and receivers but at audio frequencies in long distance telephone circuits.

The basic problem was to connect two telephones together over a single pair of wires, the amplifiers along the route being unidirectional. But, however it is arranged, there must always be a junction in the circuit at which a 4-wire circuit becomes transformed to the 2-wire both-directional circuit required by every telephone.

Now, unless the incoming 2-wire transmission line (of the 4-wire circuit) is correctly terminated impedance-wise (reflection coefficient = 0) the speech signal will be reflected back down the other pair of wires in the amplified 4-wire circuit to the telephone at the other end of the circuit. There will be an echo. Both telephones will suffer from it but not necessarily a severe problem. In fact it may be reassuring to the listener to hear his own voice - the system is working.

The real problem does not arise until an amplified 4-wire circuit becomes connected to another 4-wire amplified circuit such that the loop-gain from one telephone to the other exceeds unity. The circuit then becomes nstable - it oscillates at some indeterminat audio frequency. In engineering terms the circuit sings and becomes unusable. The singing point is when the reflection coefficient times the loop gain exxceeds unity. When a circuit sings it can be at a high level and put adjacent circuits out of operation due to crosstalk. So you see reflection coefficients and impedance matching have been foremost in design and operating engineers minds for many years.

Nuff sed. Reg, G4FGQ

Ohms are still always Ohms, regardless of what you are measuring.
And it's very interesting that the E and H fields have units of
Volts/meter and Ampere(turn)/meter, which when you divide one by the
other, you get basically Volts/ampere, just like you would in a
transmission line.

But I don't claim that a wave traveling in a transmission line is
the same thing as a wave traveling through free space.

And your example of the product of RC being in seconds actually
makes sense! After all, it is an RC time constant! The number of
seconds it takes to get to 90% charge or discharge of a series RC
circuit.

You may change Roy's mind, Richard, but he could never admit this
in public, because too many people are reading and it would make him
look bad.

I just told you that is not always true.

s11 is the reflection coefficient when a2=0

|rho| is the reflection coefficient when a2=a2

In a Z0-matched system with reflections, they are NOT equal.

You transform the input impedance of the driven stage to the optimum load of the driving stage. Whether that results in a conjugate match is completely immaterial. Trust me, I have done it .

As for the Zo thing, you are trying to misapply the formula.

BTW, the one place where you would think conjugate matching should always apply, antenna to receiver input, does not (always). Lowest noise figure often occurs at SWRs around 1.5

Why don't you try it? It is easy enough to add impedance between the
transmitter and SWR meter. Keep the power low, but exactly the same for the
two cases. In fact, all you would have to do is replace the 50 ohm line
between the transmitter and meter with 1/4 WL of 75 Ohm line.

Yes, Magid explains it thoroughly and well. His analysis includes traveling waves from the beginning to the end. It's basically the same analysis I've done myself.

What he *didn't* do was to throw the time-dependent information out the window at the very beginning of the analysis, as you've done in all your analyses involving only average power. That allows him to actually show where the energy is at every instant of time. It looks to me like his analysis is valid, so if your method leads to a different conclusion, I feel there's good reason to doubt its validity.

Y'know, if every author seems to have it wrong, considering how many really, really intelligent and learned people there are out there, and how many times their work has been carefully reviewed, have you considered for just a moment the possibility that maybe, just maybe, they have it right and you have it wrong? But if you're absolutely convinced you've discovered something that all those other folks are mistaken about, why not write your own textbook? Or at least a paper or two for the professional publications. The world will thank you for straightening them out.

Hm.

All in the same sentence, that "line losses are negligible" and "line losses will be about -3 dB"? I assume, of course that you mean 3 dB, not -3 dB. But does this mean that you consider 3 dB to be negligible? And how did you calculate that as the line loss?

I have had great luck with the AV-640 by Hy-Gain. It uses a counterpoise;
no radials required. I have mine mounted about 7 feet off the ground on a
small mast, and have been extremely pleased. It has worked very well for DX
and also has done a good job on 40 meters for local nets.

Excuse me? As a matter of fact, the way I discovered that you can
have a reflection coefficient greater than unity was to set up the
boundary conditions for a real transmission line feeding a moderately
high Q inductor and discover that |rho|>1. Up to that point, nobody
had told me it was possible. At the time, it was a somewhat
surprising result to me. Try it yourself. On a line, Vf/If = -Vr/Ir
= Zo. At the end of the line connected to an load whose impedance is
Zl, the current is V/Zl, but V = Vf+Vr, and the current there must
also be If+Ir. You should be able to reduce those to the well-known
equation for reflection coefficient, and if you plug in numbers such
as Zo=50-j5 and Zl=1+j100, you'll see that |Vr/Vf|>1. It only takes
three or four lines of simple linear algebra and perhaps plugging the
complex numbers into a calculator to find the result for that example.
Again, TRY it for yourself. DO NOT just believe what I tell you. If
you have trouble with the algebra, I'll be happy to help you out.

Cheers,
Tom

Thanks for the analogy.

One can mathematically and conceptually conceive two opposite-traveling waves that add up to the observed standing wave, and that's fine. The problem comes with assigning power or energy to the waves. Then you run into the problem of how one wave got the energy over the barrier into the pocket and the other wave took the same amount back out, without transfering any air molecules across the barrier in the process.

The average power analysis looks to me something like this. Suppose you have two batteries each with exactly 2 volts potential and zero internal resistance, with a 2 ohm resistor connected between their positive terminals. The negative terminals are connected together. You replace the battery on the left with a short (turning it off), and observe that the current through the resistor is one amp to the left. Then you hook the left hand battery back up and turn the right hand battery "off" by replacing it with a short. You observe that there's one amp now flowing through the resistor to the right. Finally, turn both batteries "on" by putting them both in place. You can use superposition to conclude, correctly, that there's zero current flowing in the resistor.

But it's silly to insist that there's a forward two watt "power wave" flowing to the right, and another two watt wave flowing to the left. You subtract one from the other and, sure enough, get zero. But are the "power waves" real? Studying and analyzing these imaginary waves is surely a lot more interesting than simply looking at the circuit and noting that the "boring" (as Cecil calls it) net power is zero. But aren't you studying ghosts?

Even more risky is adding the things. This time hook two one volt batteries in series with the 2 ohm resistor and energize one at a time. With the upper one on and the lower one "off" (replaced with a short) you get 1/2 amp. You've got a "power wave" of I^2 * R = 1/2 watt. Turn the lower one on and the upper one "off", and you get another "power wave" of 1/2 watt, in the same direction. Turn them both on, and you have a power flow of, um, 2 watts. Welcome to the new math.

> transmission line.

How do you know when the reduced units of one computation mean the
same thing as another?

An example:
The reduced units of modulus of elasticity (in/in/psi -> psi) is
the same as the units for stress (psi) and yet modulus of elasticity
is clearly not stress. And in this case, the unreduced units are
much more descriptive than the reduced units. Reducing discards
information.

On the other hand, Torque (Newton*metres) when multiplied by
Radians (metre/metre) does give Energy (N*m*m/m -> N*m), but only
after reduction. And for sure, Torque (N*m) is not the same as
Energy (N*m).

So sometimes it is appropriate to say the reduced results are the
same and some times it is not. Is there a way to know when it is
legal?

What rules have you used to conclude that reducing V/m/A/m to V/A
is appropriate?

...Keith

One last try......

Dr S: please do yourself a favor, and read this through completely *before* you hit Reply.

Let's remove the transmission lines.

You can do this without any change in the steady-state properties of the system. The right-hand one of the two lines is a 50 ohm line terminated in a 50 ohm load, so the impedance at point 3 is also 50 ohms and we can remove that line with no effect.

The remaining line is also a 50-ohm line terminated in a 50 ohm load, so that can go too... at least, it can in the idealized case where the SWR meter does do not insert any extra length of transmission line; and it sense the conditions on the line without disturbing them.

So now were down to four components, all directly coupled together with *no* transmission lines in between:
1. PA
2. SWR meter 1 (calibrated to a system reference impedance which is the same as the output impedance of the PA)
3. SWR meter 2 (calibrated to a different system reference impedance, 50 ohms)
4. 50 ohm load.

Now let's simplify it even further:
1. PA
2. Either SWR meter 1 or SWR meter 2.
3. 50 ohm load.

The real-world steady-state electrical properties of these shortened systems are still exactly the same as those of your original one.

Now what are you really saying about any and all of the above systems?

>50 ohms.
>
>
It's very convenient for this argument that "SWR" meters actually measure the magnitude of reflection coefficient, |rho|. The conversion to SWR takes place on the non-linear meter scale. (As Reg has pointed out, if you called them "rho-meters" they would have a linear scale from 0 to 1, instead of the more familiar non-linear scales of SWR or power.)

As Pozar - and countless others - correctly state, rho is a function of both the Zl that you're measuring, and the system reference impedance Zo. You cannot either measure or calculate rho without first assuming a value for Zo; not ever.

Since you have to choose a value of Zo *before* you can calibrate the rho-meter, it's not surprising that two differently-calibrated meters read differently when connected to the same physical load impedance. It's also not surprising that "re-normalizing" the Zo, either on the Smith chart or in a computer program, will predict exactly what *both* meters should read. You only need to know Zl and the two assumed values of Zo for which the respective meters were calibrated.

The same would be true even if the terminating impedance Zl was not 50 ohms as assumed above. The measured values would alter, but the ability to predict the readings of both meters would not.

In that respect, you've only been stating the obvious all the time.

The other part, the apparent belief that a rho- or "SWR" meter will change its readings according to the actual, physical source impedance from which it's being fed, remains simply incorrect. The meter is only affected by the impedance it sees at the downstream (output) side.

You can prove this very simply, by connecting various resistors between the output of the transmitter and the input of the meter. So long as you always adjust the transmitter to give the same RF *voltage* at the input of the meter - and leave the downstream side strictly alone - an ideal rho/"SWR" meter will continue to read exactly the same. I can't speak

for your real-life meter, but would expect a good one to read close to
constant.

Hmm, that question is so difficult, so let me add one more question,
to avoid frustrations.

Question:

What is the correct length of a uniform transmission line
used to feed an antenna, so that power transmission to the load
is optimized even when the characteristic impedance
(as Reg has pointed out) is noticeably reactive or not,
especially when the transmission line has some loss.

Good luck!

I should have been more specific. The line loss, in a 500 ohm open wire tuned feeder system, IF MATCHED, can be assumed to be negligible. The presence of the additional losses caused by the amplitudes of the reflected components at a VSWR of 10:1 will be about 3 dB.

Is 3 dB negligible? It's approximately 1/2 S unit. Whether or not 3 dB is negligible depends on the individual station. I get one judgment if I consider QRP and a different judgment if I consider QRO. For me, 3 dB on 75/40 is acceptable due to a single antenna limitation and 1 KW output.

Roy, thanks for challenging my 'loose language'.

"It" is not always the same thing. What I am saying is that nobody's perfect, nobody knows everything, and 1000 years from now, most of what you and I believe today will be obsolete.

For instance, Ramo & Whinnery use the square root of the ratio of reflected power to forward power to define the reflection coefficient. Shortly thereafter, they use the reflection coefficient as the cause of that power ratio. So in essence, they are saying that the reflection coefficient causes itself.

Another example from this newsgroup. After standing waves have been caused by the superposition of forward waves and reflected waves, they somehow become self-sustaining without the forward waves and reflected waves.

Proposing waves that exist without energy seems more problematical
to me. And nobody has come up with an explanation of how standing
waves can exist without forward waves and reflected waves in a
single source, single feedline, single load system. Seems to me,
that is an absolutely necessary first step in proposing self-
sustaining standing waves.

> The average power analysis looks to me something like this. Suppose you
> have two batteries ...

In a typical ham installation, there is only one source and all system
energy is supplied by that single source. Please limit your examples
to one source to adhere to reality. Having to change the example
away from reality to multiple sources to make a point is a weakness,
not a strength, in the argument. In a typical ham installation, instant
energy is NOT available since the source is nanoseconds away. Any
energy needed instantaneously must already be there.

Reg, this "Establishment" is something that you just invented. The audacity is yours.

Yes, there are people on this newsgroup who agree on lots of technical points. And yes, they are often quite insistent about it.

(At this point, I'll change to "we", because I am one of the people we're talking about. And despite his chosen role as maverick, provocateur and general gadly, so too is Reg ;-)

Nobody knows everything, but each of us has been around for long enough to have covered most of the same territory, and to have made all the common mistakes. But we've also been around long enough - and been persistent enough - to have come out the other end with some correct answers.

(Here comes Philosophy of Science in two paragraphs. Please don't give me a hard time over the things I'm going to leave out.)

What's a correct answer? One that accurately describes external, physical, observable, measurable reality, as nearly as we can measure it or need to know. People who take that view are not too comfortable with approximations and half-truths, because sooner or later we're going to be caught out by a new situation where the "nearly correct" answers don't work any more. In the long run, it's simply easier to work out a correct answer that can be trusted.

Each of the people Reg is talking about (in fact, especially Reg himself) worked out many of those answers for ourselves, way before we met on the Internet. But when we did meet, it wasn't at all surprising to find ourselves agreeing on so much. That's because all correct answers are describing the same physical reality, so they *have* to agree. The only allowable difference is to choose different viewpoints upon the same reality; but if they are correct, all those alternative viewpoints still *must* be consistent with one another - they must *not* contradict in even the smallest detail (unless it's acknowledged to

involve an approximation).

Those rules are rigid, but nobody made them - reality did. The only available choice is whether to accept them and stick by them, or to sometimes let them slide. I choose to accept them, as much as I possibly can, because it's actually easier in the long run. If someone else's better logic forces me to re-evaluate, that's really not a problem because I'm better-off than before.

Yes, people like that can be rather insistent! But it's not because we want our personal faiths or beliefs to prevail - it's not about us at all. It's because we want external, physical, observable, measurable reality to prevail.

Cue for somebody to pipe up about quantum physics, Heisenberg, uncertainty and all that. There are certain areas of science and engineering where these apply and even dominate, and mean that certain things are fundamentally un-knowable. Antennas, transmission lines and electronic engineering are *not* one of those areas. It's an excellent approximation to say that everything in these areas of physics and engineering is fixed and "real", and - if we work hard enough at it - knowable.

The exceptions, such as noise and the internal physics of semiconductors, can all be treated by engineers as macro-scale observables. A good example is the tunnel diode, which relies on a probabilistic quantum phenomenon that just can't happen according to classical science... but at the engineering level you can still rely on the device data. You don't see "Probably" stamped on each page.

Cue now for someone else to pipe up "But we don't know everything yet." No, we don't... but for every genuine new discovery, there are billions of mistakes, experimental and logical errors. When straightened out, these simply confirm that what we already knew is correct. You'd better learn to trust that body of existing knowledge much more that you trust yourself! I certainly do, and again life is easier as a result.

The good thing about the Internet is that we can all learn much faster than before. I certainly have. The bad thing is that we no longer make our mistakes in private. Stuff that used to end up as crumpled balls of paper, to be thought about more clearly tomorrow, is now being published every night to be read by thousands of people and archived forevermore. It's becoming harder and harder to identify the good information among all the rest.

To anyone who has already made those same mistakes, it seems such a waste to see people wandering off and doing it all over again. It's very hard to stand by and let it happen...

> dissipated in the load?

==========

The answer is perfectly obvious. Everybody who didn't see it immediately should kick themselves - hard!

For max power into the load, make the load impedance equal to the CONJUGATE of the impedance looking back into the line. There will be big standing waves at the load end of the line.

For exact load value it is necessary to know line length, propagation characteristics and the internal impedance of the source.

But when line attenuation is more than a few dB the impedance looking back into the line is Zo and maximum power is obtained with a CONJUGATE MATCH as always.

If the line is terminated with its own impedance, ie., Zl = Zo, there will be NO standing waves and line loss will increase.

To demonstrate the foregoing, download program COAXPAIR from website below, enter nominal HF Zo = 50 ohms, inner conductor diameter = 0.8mm for RG-58, frequency = 1000 Hz, length = 30,000 metres = 20 miles, and terminate the line with its own input impedance which is also Zo. Then terminate it with the conjugate of its own input impedance and keep your eyes on line loss in dBs. Also see what happens to line loss with shorter lengths.

Dr. Slick wrote:
"Therefore, the reflected voltage can never be greater than the input voltage for a passive network, and the reflection coefficient can never be greater than 1 for such a case."

Terman, despite Reg`s disdain for experts, seems to agree with Dr. Slick. Here is Terman`s gist:
1. The reflected wave is identical to the incident wave except it travels toward the generator.
2. Ereflected / I reflected = -Zo. Just as Eforward / I forward = Zo
3. Line loss causes the reflected wave to decline as it travels toward the generator.
4. Phase of the reflected wave drops back as distance back from the load increases.
5. Volts at the load are the sum of the incident and reflected wave volts. Likewise for currents.
6. E/I at the load equals Zload.
7. The vector ratio Ereflected / E incident erquals rho, the reflection coefficient..
8. In a lossless line, rho is the same everywhere on the line.
9. The effect of a reactive load is merely to displace the SWR pattern on a transmission line.
There is no opportunity in the stated conditions on a transmission line for a reflected voltage to exceed the incident voltage or for the reflection coefficient to exceed one (1).

Best regards, Richard Harrison, KB5WZI

> there is no energy flowing. Period."
>
> Yes there is energy flowing, and it is flowing in both directions if it
> is flowing in one direction. Otherwise there would be no standing wave.

This view that there is energy flowing in both directions at the same
time
leads to some strange conclusions.

The directional wattmeter uses the following expressions to compute its
displayed value:
Vf = (V + IR)/2
Vr = (V - IR)/2
where V and I are the instantaneous voltage and current at the same
point
on the line and then computes power from:
Pf = average(Vf**2/R)
Pr = average(Vr**2/R)
Appropriate scaling (which we'll ignore for simplicity) is needed
depending on the characteristics of the voltage and current sensors.

Let's apply these expressions to some simple examples.

Connect a length of 50 Ohm transmission line to a 9 Volt battery and
wait
for the transient to die:
Vf = (9 + 0)/2 -> 4.5 V
Vr = (9 - 0)/2 -> 4.5 V
Pf = 0.405 Watt
Pr = 0.405 Watt
Disconnect the battery and the capacitance of the line remains charged
to
9 Volts. Are you really quite comfortable with the notion that this
line,
charged to 9 Volts, with 0 current everywhere has 0.405 Watts flowing
forward canceling at all points the 0.405 Watts flowing in reverse?

Others have stated that lamp cord has an impedance of about 100 Ohms.
Assume this to be correct.
With a table lamp plugged in but the lamp turned off:
Vf = (120 + 0)/2 -> 60 V
Vr = (120 - 0)/2 -> 60 V

Pf = 36 Watt
Pr = 36 Watt
Again, are you comfortable with this conclusion?

How about phone lines (phone on hook) at 600 Ohms and 48 Volts:
Vf = 24 V
Vr = 24 V
Pf = 0.96 W
Pr = 0.96 W
In a 400 pair cable there is 384 Watts flowing in the forward and reverse direction. From a hundred thousand line central office we get 960 Kilowatts forward and reverse, when the current is zero, everywhere. Comfort level?

With the forward and reverse power view, to completely understand the behaviour of the circuit, we need to know Z0 or we can not compute these forward and reverse powers which seem to be fundamental.

Consider a flashlight with the lamp off: the wire twists and turns and has a very non-constant Z0. While computationally tedious, it is possible to determine Pf and Pr at every point along the wire. Isn't it necessary to do this to obtain a complete understanding of what is happening in the circuit, if Pf and Pr are flowing? If not, why not? The necessity for doing this is the logical conclusion of the Pf and Pr approach.

Presented with a wire charged to high static voltage, what is Pf and Pr? Presented with a sphere charge to a high static voltage, what is the Pf and Pr?
Presented with a simple length of wire, how much power is flowing?

Similarly for a capacitor. The plates of a capacitor must have power reflecting in all directions even when it is just charged to a constant voltage (according to the Pf and Pr theory).

Given these bizarre results it would seem wise to limit the application of the watts indicated by a directional 'watt'meter to those things which are proper and not assume that it necessarily means that there is real power flowing.

==========

Dear Dr Slick, it's very easy.

Take a real, long telephone line with Zo = 300 - j250 ohms at 1000 Hz.

Load it with a real resistor of 10 ohms in series with a real inductance of
40 millihenrys.

The inductance has a reactance of 250 ohms at 1000 Hz.

If you agree with the following formula,

Magnitude of Reflection Coefficient of the load, ZL, relative to line
impedance

= (ZL - Zo) / (ZL + Zo) = 1.865 which exceeds unity,

and has an angle of -59.9 degrees.

The resulting standing waves may also be calculated.

Are you happy now ?

Reg, G4FGQ

The transient is the only part of your proposal for which the 50-ohm
surge impedance has meaning. That`s why it`s called the "surge"
impedance.

The 50 ohms is Zo and equals the sq.rt. of Z/Y, or in a perfect line
this is sq. rt. of L/C.

L and C require an alternatng current (changing, not static) to produce
reactance, so the d-c calculations are meaningless to Zo.

Richard I am very familiar with all you write.

But I have one question: if the 'transmission line' is very short so that the 'significant portion of a wavelength' criteria is not met, then the capacitive reactance of the line and any inductive reactance in the load and the effective Q of the circuit may all come into play. Is it possible for a resonant condition to exist? If so, does the reflection coefficient have any significance?

Not an 'of course' at all. In general in circuit analysis, one can
use superposition to evaluate voltages and currents, but it is quite
unusual for powers to sum properly at the same time. This works for
Vf, Vr, Pf and Pr in a transmission line because
Vf (= (Vinst + IinstR)/2)) and Vr (= (Vinst - IinstR)/2)) are
defined in terms of the same two variables but one is a sum and the
other is a difference.

An intriguing thought, but transmission lines work perfectly fine with
pulses, step functions and DC. In particular, the expressions for Vf and
Vr work quite well at zero frequency, so an explanation which only works
for RF would seem to be incomplete.

Try thinking about how charge moves on a transmission line. These
solutions are not not constrained to just RF.

Again, generally not true. There is something quite specific about
the derivation of Vf and Vr which makes it so.

Well, I always thought the movement of energy was constrained to the
speed of light. If it changes direction every quarter cycle, then it
can not move more than 1/4 quarter wavelength or about half a meter
at 150 MHz.

> Since water molecules cannot travel at the speed of sound in the ocean,

I would not argue that. I am not sure what I wrote to lead you to that
conclusion.

Oh, the waves are there all right, if you choose to model it so. But,
they
are waves of voltage and current, not power.

As to models, the power folk model their lines as a voltage and current
which are out of phase. At 60 Hz the lines are not long enough to

observe the standing wave, so they have little interest in this
approach.

> What exactly, keeps energy from crossing the boundary?

The same thing that stops the current and energy flow into a capacitor
when the capacitor has charged to the supply voltage.
The voltage on the capacitor and the supply are the same, no current
flows and no energy moves.

Try thinking about the line in terms of circuit theory and charge.

A transmission line with distributed capacitance and inductance is
somewhat more complex than a voltage source and a capacitor. The
distributed capacitance and inductance form resonant circuits which
transfer energy between capacitance and inductance. Just like a
circuit, if you short the line at any point where the voltage is
always zero, or open it at any point where the current is always
zero, nothing is changed. The voltage and current distributions
remain the same.

> Here is an example.
>
> source-------------50 ohm coax--------------+----1/4WL stub-----open
>
> What mechanism of physics keeps energy from crossing the '+' point? Note
> that there is no physical impedance discontinuity at point '+'.

The voltage is always 0 so from the most basic of circuit theory,
the power is zero, so the energy flow is 0. I have some difficulty
articulating what happens at a current maximum. But if you will permit
me to move the question back another quarter wavelength to a voltage
maximum and current minimum, the answer is easy. The voltage on both
sides of the current minimum are always the same so that no current
flows, hence no energy flows.

>
> All you have to do to convince me that you are right is explain exactly
> how standing waves can be sustained without a forward wave and a reflected
> wave (in a system with a single source, single feedline, and single load).

Though an intriguing question, this is not what I am attempting to convince anyone of. Rather I disagree with the view that in an open or shorted ideal line, energy flows to the end, is reflected back, flows back to the start and is reflected again. Repeat. To be even a bit stronger, ENERGY does not cross any point where the voltage or current is always 0. This is so that the expression P = V x I can remain true.

As to your question on standing waves, when a resonant circuit is exited with an impulse function, a sinusoidal voltage and current occur in the circuit. It does not seem much of a stretch to find a sinusoidal spatial distribution of voltage and current in circuit constructed of distributed capacitance and inductance (i.e. a transmission line).

Opps! Actually, for one RC time constant, it's about 36.79% of the
initial surge current when charging, or 63.21% of the final charged
voltage at t=infinity (it theoretically never reaches a full charge,
as you obviously know).

The point is that the units of R*C lead to units of seconds, which
is exactly what it should be. There is order to the universe!
Sometimes...

Deacon Dave wrote:
"Is it possible for a resonant condition to exist " (with a short cable)?

If the cable is too short to enforce Zo, the source for Zload is not necessarily a resistance and the load for the source can be resonant.

A short-circuited transmission line, shorter than 1/4-wavelength, is an inductive reactance. An open-circuited transmission line, shorter than 1/4-wavelength, is a capacitive reactance.

A transmission line is not required for mismatch between source and load. If a source can only supply a certain voltage to current ratio, and it`s different from the immutable Zload, you have a mismatch and a surplus of volts or amps which are rejected by the load.

The simple analysis of a series-resonant situation involving line inductance and a load capacitance is that volts across either is (I)(Z). The Z`s are about equal at resonanvce.

Trivia: 1/8-wavelength of line has a reactance which is equal to Zo.

Best regards, Richard Harrison, KB5WZI

>How do you know when the reduced units of one computation mean the
>same thing as another?

They are ALWAYS fungible. You can certainly munge up operations to prove otherwise, and it is easy to do with some really long chain of computations.

I would suggest you investigate any of the several really good Mathematics programs, one being Mathcad which offers a huge repository of such Units tools that it uses to the enormous and enthusiastic response by engineers and scientists. There greatest asset is in allowing, you, the user, to enter your measurement in whatever Units your profession is comfortable with, and marry them into a novel situation at the interface to another discipline. How much horse power generator is needed to supply electrical power that is required to move a speaker cone how many inches to compress air to what sound pressure level for it to be just barely discernable to the average listener? That standard could be described as the force necessary to move the eardrum the same distance as the diameter of an Hydrogen Atom.

The Elasticity Modulus is described in kg/mmï¿½ which is not quite MKS, but performing the necessary operation to make it so does not remove any information whatever. If we stick with electronics and discuss the stress mechanics of piezos (crystals), then stress can be described in terms of
(volts/meter) / (newtons/meterï¿½)
>
>On the other hand, Torque (Newton*metres) when multiplied by

This is negative evidence? It is more a clouded argument.

> And for sure, Torque (N*m) is not the same as
>Energy (N*m).

You are confusing Work and Rotational Statics as being different.
Can you distinguish between Kinetic Energy and Potential Energy
described in mechanical units? If so, both are used to describe the
complete Work equation:
(KE2 - KE1) + (PE2 - PE1) = 0
>
>So sometimes it is appropriate to say the reduced results are the
>same and some times it is not. Is there a way to know when it is
>legal?

Strictly speaking from the point of legality, it is demanded of
Professional Engineers by the National Institutes of Science and
Technology (what was called the National Bureau of Standards or NBS
years ago).

This means that ANY P.E. that describes a physical relation that does
not conform to these scientific concepts, and damage results to that
Professional Engineer's customer, then that P.E. is liable in a court
of law. This form of legality is the whole point of being P.E.s and
the government making the demand that P.E.s be part of describing
engineering codes and performing design review.

Anyone here who has put up a tower has had to jump through this hoop.
One of their principle concerns is found in the CM or Center of
Moment. The employment of Units transformation and reduction is part
and parcel to their activity (How tall? Length. How heavy? Mass and
the constant of Gravity).

The ONLY reason the city, or county insists on this report is to have
someone take the insurance hit if there is an error in meeting code.
Was your tower too tall for the weight of that long lever arm (your
antenna boom and elements) that also created a torque? Did it snap
with wind load? Did the guys snap through poor tensioning? Every one
of these uses Units that eventually boil down to one of the
tower/beam/guy specifications expressed in identical Units. There is
no other way for anyone to put their name to a report qualifying your
tower otherwise - why would they want to jack up their malpractice
payments? And it would be their insurance, not the city's if your
tower fell on a citizen and their heirs sued because of the city's
permission to you to erect it. This is called negligence and is why
your homeowner's insurance would walk away from you for a tower
collapse where the tower was not inspected to code.

If the P.E. met the standards of transforming between various systems
and observed the Physical Constants defined by NIST, then the P.E. is
NOT liable. If the P.E. is not liable, neither is the city/county.
If the P.E. and government are not liable, you have a problem.

>
>What rules have you used to conclude that reducing V/m/A/m to V/A
>is appropriate?
>
>...Keith

Hi Keith,

You probably have no concern for the monolog about P.E.s or you put it behind you long ago. Or so you and others might presume. That's fine and this divergence off into mechanics may help some see the relations but to answer your last question and keep it within the context of the subject line, we should look at another reference that is less remote than NIST and closer to antennas:
"Fields and Waves in Communication Electronics," Ramo, et al.

From page 3 (yes, pretty up front):

"Various systems of units have been used, but hat to be used in this text is the International System (SI for the equivalent in French) introduced by Giorgi in 1901. This is the meter-kilogram-second (mks) system, but the great advantage is that electric quantities are in the units actually measured: coulombs, volts, amperes, etc."

This reference proceeds to describe those Physical Constants and their relations that define Permittivity that I have already fully revealed in a recent posting. If we were to proceed to page 71:

"The quantity known as the magnetic field vector or magnetic field intensity is denoted H [sound familiar folks?- rwc] and is related to the vector B define by the force law (2) through a constant of the medium known as the permeability, ï¿½:
B = ï¿½H
...
"In SI units, force is in newtons (N), Current is in amperes (A) and magnetic flux density B is in tesla (T), which is weber per meter squared or volt second per meter squared and is 10^4 times the common cgs unit, gauss. Magnetic field H is in amperes per meter and ï¿½ is in henrys per meter. ...
The value for ï¿½ for free space is
ï¿½0 = 4 ï¿½ pi ï¿½ 10^-7 ï¿½ H/m"

So, there you have it. Absolutely identical to my other posts. The RF engineering community's usage of free space Z is in full compliance with the standards established and maintained by NIST. Both these sources and standards are employed by commercial engineers and Professional Engineers alike. It makes no sense to do otherwise unless you want to start your own system of measurement that allows a CFA to be 110% efficient. We get many efficiency claims that can ONLY be judged through these associations described.

The chain of relationships proves that the "ohms" described by the Z of free space are identical to the "ohms" used for ANY electrical measurement, among which are the resistance determination of an antenna (for any feed), or the resistance presented by a carbon composition resistor.

Hi Dave,

Depends on two things. The degree of resolution you demand and the
possibility of end effects (would it be easier to go around instead of
through?).

When I was at the Metrologist Bench, I would be asked "how accurate
can you measure this?" My response was "How much can you afford?"

Not really. Look at this:

http://hyperphysics.phy-astr.gsu.edu/hbase/permot3.html

If you notice, the strain is = delta L/ original L, so the strain
is dimensionless. So Young's modulus actually seems to represent the
N/m**2 (PSI) that is required to elongate something to twice it's
original length: delta L = original L, so that the denominator is 1.

interesting that you bring this up.

> On the other hand, Torque (Newton*metres) when multiplied by

>

Hunh?? how did you get radians = m/m?

Look here:

http://www.sinclair.net/~ddavis/170_ps10.html

I admit that this page reminded me that radians are
dimensionless.

So the torque times radians just gives you the work done, which
is in the same units as torque by itself. it's a bit confusing, but
Rotational units are used differently from linear ones (you have the
moment arm), so linear units are force is Newtons or lbs, and work is
in Newton*meters or ft*lbs.

I'm not totally sure, but the reason for this discrepancy seems
to be related to the fact that upon each rotation, you end up at the
same point, so in a certain sense, no work is done. But the crux is
that angles are dimensionless:

http://mathforum.org/library/drmath/view/54181.html

But in either case, rotational or cartesian, the Newton is still
a Newton, and so are the meters.

> So sometimes it is appropriate to say the reduced results are the

>
> ...Keith

Basic algebra and cancellation of units. When have you found it
not to be appropriate? I'll admit that it can be a bit confusing
going from cartesian to rotational, and you have to understand the
context, but the UNITS ARE ALWAYS THE SAME. Isn't this the crux of
science and math? That we have certain standards of measurement, so
when we say it's a meter, it's a meter? God, i hope so.

Gary -

Look at these web sites.

L.B. Cebik, W4RNL basics on the HB9CV antenna.
The HB9CV version of the 2-element phased array appeared in 1961. In Europe, some writers refer to almost any 2-element horizontal phased array as an HB9CV, while the English-speaking world tends to refer to the ZL- Special to mark the genre of antenna. The HB9CV version of the antenna and many variants are widely used in Europe, with Christmas tree stacks for 20- 15-10 meters. Users swear by them, claiming near to, and sometimes better than, 3-element Yagi performance.
http://www.cebik.com/hb.html

There are a number of "copies" and homemade versions
of this antenna on the market
http://www.page.sannet.ne.jp/ja1hwo/ap03/64elhb9cv_e.htm

http://www.alfa-tango.com/ant/hb9.php4

Make sure that the former owner did not "modify" this antenna
http://davidkearns.co.uk/G8TTI/HB9CVdetails.htm

http://www.wimo.de/verteiler-e.htm?s37a_e.htm

This is the 28 MHz version

You would then have either:

PA--+SWR meter1+50 ohm dummy load
(same Z as PA)

1 2

In which case, this would be equivalent to re-normalizing the
Smith, and as you change the Z of both the PA and SWR meter, you will
absolutely measure a different SWR (you will measure the reflected
power at point 2), going into 50 Ohms believe it or not. Please get
MIMP, it's a free program from Motorola.

Or:

PA--+SWR meter1+50 ohm dummy load
(50 Ohm meter)

1 2

In which case, you would NOT measure the reflected power at point 1
(from the discontinuity from the PA to 50 ohms, because this is before
the meter.
This is the case you guys are talking about, WHICH I TOTALLY AGREE
WITH, as the source Z shouldn't affect the SWR meter in this case.

The point is that it depends on where you measure it!

But then I was not talking waves, but charge. The waves are a
manifestation of the changes in the charge distribution.

Perhaps. Or they misspoke. Or they have been misinterpreted. Or perhaps
they are wrong.

An intriguing result, isn't it? But clearly energy does not need to flow
in the same direction as the information.

> One point. The power is not Vavg * Iavg.

Correct. I hope I have not given any other impression. For the most
part in my discussions I mean instantaneous power, since conversion to
average loses too much information to enable understanding.

> The power is Vavg*Iave*cos(theta).

This, of course, depends on the waveform and certainly applies to
sinusoids. More complete is to integrate Pinst = Vinst * Iinst and
divide by the time (often chosen, for convenience, to be one cycle).

But for the most part, greater understanding will arise from sticking
with instantaneous energy flow.

> All up and down a shorted lossless transmission line, theta is equal to

> degrees out of phase with the current in a lossless shorted feedline.

But at certain points (1/2 wavelength apart), the voltage IS always 0
so the energy flow IS always 0. Unless you are prepared to discard
Pinst = Vinst * Iinst.

At other points the energy flows forward (when V and I have the same
sign)
for part of the cycle and flows backwards (when V and I have different
sign)
for other parts of the cycle.

Well I suppose I don't mind so much if it is ghosts making the round
trip as long as they don't contain energy. It is certainly true that

the changes in the energy distribution make some round trips. But that is not the same as saying the energy makes the trip.

Nope. Zo can be anything you want, especially interstage where
you usually don't have/need a 50 ohm transmission line.

Who told you about the lowest NF at a 1.5 SWR? Can you give us a
link?

Why would reflected power at the receive end benefit NF?

Thank you Richard! You and Richard Clark should be named twin
pillars of reason in a sea of irrationality spurred by the Lust of
Always Being Right.

This is a very important point, that the reflected voltage will
be received by the same impedance that launched it to begin with.

It's really an elegant and simple equation:

[s11]**2 + [s21]**2 = 1

For a lossless passive two port network, where the brackets
indicate magnitude only. If the sum of the squares is less than one,
the network has losses.

Amen, Brother Ian. Well, the reality WILL prevail. Some may disagree with it, but it's there for them to see if they look with an open mind. I know for certain that Roy is motivated to post here at least in part to help insure that the newcomers at least have a realistic view of reality to pick from, among those presented. I suppose some of the rest of us have the same motivation. Richard Feynman's (ghostwritten) book, "The Pleasure of Finding Things Out," expresses the concept of opening one's self up to learning through thinking and observing very nicely, I think. I'm always happy to learn that I've been WRONG about something, because after I make the proper correction, other pieces of the puzzle fit together better. It's like being bothered by a piece of a jigsaw puzzle which doesn't quite fit, and then finding the right one: it helps bring order to my world. And when pieces fit all very nicely together, you are much more certain that they are "right," at least at the level you're observing, even when there is possibly an even more unifying viewpoint that could be taken.

Cheers,
Tom

Everything's fine down to point 8, but it's for a line with loss, and
therefore with a characteristic impedance which is reactive, that you
get magnitude of rho greater than unity. You have all the info you
need to show that to yourself with the first few points and additional
fact that load current equals the sum of Ifwd and Irefl at the load.
Just work through the simple algebra to verify the well-known equation
for Vr/Vf, and then plug in Zo = 50-j5 and Zl = 1+j100 and evaluate
the magnitude of Vr/Vf at the load.

Cheers,
Tom

You really don't have a choice, you have a need. What is the
polarization of the receive antenna? The two should be the same. If
they are not, your range will plummet to a few meters.

>
>- Should the antenna be as long as possible, or a harmonic division of
>the ideal "30-35 cm"?

Close is enough. If you were off by 20% and it didn't work, then you
have far more problems than the length of the antenna.

>
>- Also, what material should the antenna be made of? And what shape
>(thin/thick, tube/square, solid/hollow)?

thick (thin is ok), tube or square, hollow (solid is ok). Use a
conductor, copper is the easiest to come by, but if you are thinking
metal tape, try it, many successful designs work with it just fine.

>
>- Can I use a loop antenna?

Sure, but it is a lossy loop if it is wrapped around your electronics.
Even with this said, it may not matter anyway, or your problems are
worse than the loss.

>
>(I hope this question is not malplaced in this forum. Any thought on
>any point above is most welcome!)

Hi Bjï¿½rn,

You are in the right place. It's just others' attentions are fixed to
counting the number of angels dancing on the head of a pin. :-)

I would point out that your original requirement stated you needed a
whip of wire such-and-such long. This presumed that the equipment it
is connected to provides a stable ground reference for it to operate.
Ground for you can mean many things, but for handheld devices (which
have no connection to earth), this ground is simply the bulk of
electronics in the package. This is what makes wrapping an antenna
around them so risky. Many designers do this though, and it works;
however they only want 20 foot range (across a room) and are happy to
sacrifice the remaining 180 feet to achieve it with the antenna
hidden.

If this is point-to-point connection (neither the receiver or
transmitter move), then maximize your receive antenna by using what is
called a yagi style design. This will recover the transmitter's loss
of such hidden antennas and return you your 200 foot range.

Yes, and no. It was length per length, not, for example, volt per volt
or
pound per pound or ...

So dimensionless quantities are not all the same, even though they are
all dimensionless.

Length of arc divided by radius in MKS units. How quickly we forget when
we get in the habit of leaving out all the units.

After multiplying Torque by Radians, you have computed the length
along the arc through which the force has acted -> energy, of course.

> > ...Keith
>
> Basic algebra and cancellation of units. When have you found it
> not to be appropriate?

It is not appropriate to consider Torque and Work to be the same, though they have the same units.

It is not appropriate to consider modulus of elasticity and pressure to be the same, though they have the same units after simplification.

But after multiplying Torque times Radians it is necessary to simplify to discover that Work is the result.

I conclude that simplification is sometimes necessary and appropriate but other times it is not. I am having difficulty knowing how to know when it is appropriate.

This brings us back to the Ohms of free space and the Ohms of a resistor.

While I don't know whether they are the same or not (and opinion seems divided), it is clear that arguing that they are the same because the units (after simplification) are the same is quite falacious. On the other hand if the units were different, it would be clear that they are not the same.

> No, simple multiply.

Well, then your equation is wrong. It should contain phase. The
power is V*I*cos(theta) which is known to be *AVERAGE* power since
V and I are RMS values. When the total voltage is zero and the total
current is 2*I, the phase angle is still 90 degrees for a lossless
stub.

> In general in circuit analysis, one can
> use superposition to evaluate voltages and currents, but it is quite
> unusual for powers to sum properly at the same time.

They sum perfectly if interference term is taken into account. The
equation becomes something like, e.g.

P1 + P2 + constructive interference = total forward power

P3 + P4 - destructive interference = total reflected power.

This is all explained in _Optics_, by Hecht.

> Oh, the waves are there all right, if you choose to model it so. But,
> they are waves of voltage and current, not power.

How do those waves ever come into existence without a power
source? During the first two seconds when a 100w transmitter is
driving a one second long lossless line, it shoves 200 joules
into the line. What happens to that 200 joules?

Of course, something is changed dramatically. You have introduced an extreme impedance discontinuity where there was none before. How you can assert that nothing is changed when something has changed as much as it possibly can change is pretty strange. You have gone from 100% transmission of waves to 100% reflection of waves.

> sides of the current minimum are always the same so that no current
> flows, hence no energy flows.

Exactly what mechanism of physics allows a non-changing characteristic impedance to cause reflections? There is no impedance discontinuity. Therefore, there are no reflections. What you need to realize is that no *NET* energy flows but the forward wave has absolutely nothing to interfere with its flow. The reflected wave has absolutely nothing to interfere with its flow. The total voltage and total current is *caused* by the waves. Therefore, the ratio of the total voltage to total current cannot affect their own cause. One more example of confusing cause and effect. All this is obvious when observing ghosting during a TV experiment.

> remain true.

You are again confusing the energy carriers with the wave energy. They are not the same thing. The energy carriers don't cross the boundary (except for random occurrences). But there is no physics mechanism to stop the wave energy from crossing the boundary in both directions. There is nothing there that can reverse the momentum of the waves.

The easiest way to view your mistake is by putting a directional wattmeter half way down a stub. Guess what you will read? We had this discussion on this newsgroup a few months ago. No one could prove that the mouth of the stub has any effect at all on the forward wave and the reflected wave.

> distributed capacitance and inductance (i.e. a transmission line).

The stretch is finding a physics mechanism that will create and sustain
standing waves without a forward wave and a reflected wave. Please describe
in detail how it is done. You need a physics mechanism capable of reversing
the momentum of waves in a constant Z0 environment. Good luck on that one.

Yes, I know that. When are you going to stop confusing the charge carriers with the waves? :-) The charges have exactly as much to do with the waves as water molecules have to do with water waves. Water molecules don't cross certain boundaries but that doesn't keep tsunamis from wiping out an island.

> Correct. I hope I have not given any other impression. For the most
> part in my discussions I mean instantaneous power, since conversion to
> average loses too much information to enable understanding.

Instantaneous power is essentially useless to this discussion according to Hecht in _Optics_. Here's a quote: "Since the power arriving cannot be measured instantaneously, the detector must integrate the energy flux over some finite time." Irradiance is *average* power.

> But for the most part, greater understanding will arise from sticking
> with instantaneous energy flow.

I hope, for your mental health, that you don't really believe that. :-) If it doesn't work in optics, there is no reason to believe that it will work for other photonic waves, including RF.

> But at certain points (1/2 wavelength apart), the voltage IS always 0
> so the energy flow IS always 0. Unless you are prepared to discard
> Pinst = Vinst * Iinst.

The *NET* energy flow is zero. The component energy flow encounters absolutely nothing that can change its momentum. There are NO impedance discontinuities to cause reflections. It would take a Transmission Line God to do that.

> Well I suppose I don't mind so much if it is ghosts making the round

> is not the same as saying the energy makes the trip.

I had hoped metaphysics wouldn't enter into this discussion. Wave modulation without energy is certainly in the realm of the supernatural. The reflection model is perfectly consistent. All other models seem to contain contradictions. The wave reflection model was fully understood in the 1950's and, at HF, has not been proven wrong. Why discard it?

Richard Clark wrote:
"So how do the "ohms" of free space differ from the "ohms" of a quarter wave monopole`s radiation resistance?"

Terman says something like: the radiation resistance has a value that accepts the same power as the antenna takes when the equivalent resistor is placed in series with the antenna."

Roy Lewallen has already said that the resistance of free-space is the ratio of the E-field to the H-field. Fields relate to the forces they exert. No amps in empty space which has no electrons. Only when a conductor is inserted is there a path for electrons to travel in.

Evidence that antenna impedance does not define radiation is the identical radiation produced by antennas which are very different.

The folded monopole and the quarter-wave vertical are quite different. The monopole is a small squashed loop. The quarter-wave vertical is a single rod. Feed point resistance is 150 ohms for a typical folded unipole and it is 28 ohms for the typical quarter-wave vertical. A look at Arnold Bailey`s catalog shows identical radiation patterns and gain for both antennas.

Best regards, Richard Harrison, KB5WZI

Why do you need to obfuscate the discussion by resorting to DC? Why can't you explain things using RF? One previous poster refused to discuss a single source system for some reason. Since reactance disappears during DC steady-state, the relevance of a DC example is certainly questionable. Hint: The Z0 of a piece of coax at DC is NOT 50 ohms.

Reading Keith`s posting, somebody wrote:
"The power is Vavg"Iavg"cos(theta)"

This is mistaken. The average value of a sine wave is 0.637 times the peak value. We use 0.707 toimes the peak value of a sine wave, the rms value, which is the effective value, that is, it is as effective as d-c in making power calculations.

The average power must be the same as d-c. This is peak volts times peak amps divided by two, or 1/2 the peak power. 0,707 x 0.707 = 0.5, so we use rms, not avg. volts and amps to calculate average power, which is the same in capability when producing light and heat from resistive devices.

Best regards, Richard Harrison, KB5WZI

I see your confusion and apologize for not being completely clear.
When I say P = V * I, P, V and I are instantaneous values, the only
ones worth exploring if an understanding is desired.

Well, if you do a bit of fudging you can always make it work. But
I do not observe these fudge terms in the expressions related to
forward and reverse power in transmission lines.

> P1 + P2 + constructive interference = total forward power
>
> P3 + P4 - destructive interference = total reflected power.

Of circuit theory I have a reasonable grasp, optics I leave to others.
It seems to me it should be possible to analyze these linear time
invariant circuits without having to resort to optics.

As mentioned previously: stored in the line and moving back and

Back in basic circuit theory, some years ago, it was permitted to
short points of equal voltage and open conductors with no current.
Has this changed in the intervening years?

> You have introduced an
> extreme impedance discontinuity where there was none before. How you

Because the observed voltages and currents are the same. The circuit
has been replaced by one which is indistinguishable from the first.

> You have gone from 100%
> transmission of waves to 100% reflection of waves.

An intriguing assertion, but one which can not be demonstrated through
any observations made on the circuit.

I am not sure why you are looking so hard for reflections. I am not
attempting to claim that there are any. I simply claim that no energy
can cross the boundaries because the current or voltage is always 0.
Basic electriciy. This says nothing about the presence or absence of

reflections or whether there is a mechanism to prevent the energy
crossing the boundary or it just happens through the dynamics of the
distributed capacitance and inductance.

Oh, I fully understand what a 'directional watt' meter will indicate.

May I suggest that you perform the same experiment with a real
instantaneous
watt meter: one that computes P from V * I. Observe the time variation
of
the real energy flow. When does it flow forward, when does it flow back.
Integrate to obtain the average. Repeat at the quarter and halfwave
points.
Repeat for a line terminated in other than Z0 but not open or short.

Rationalize the observations from the real watt meter with those from
the 'directional watt' meter.

It is also instructive to perform the above experiment with an
instantaneous 'directional watt' meter. That is, what are the
observations
before averaging has been performed and how do they vary with time.

> We had this discussion on

Keith wrote:
"While I don`t know whether they are the same or not (and opinion seems divided), it is clear that arguing that they are the same because the units (after simplification) are the same is quite falacious."

Fields and the volts and amps they can produce are locked together. An example is the 1-meter wire best placed to be swept by a radio wave of 1-millivolt per meter will have 1-millivolt induced in the wire.

The field is not identical to a voltage because it requires no conductor to exist, but it has the same value and follows many of the same rules.

Mostly because a sensible answer should be able to explain from
DC to RF. If it only works at RF but collapses with the much
simply DC, then the answer seems suspect.

Why is there so much protestation about having the answer explain
DC behaviour as well?

> Why can't you explain things using RF?

I like my answers to explain the more complex (RF) as well as the
simpler (DC). As well, applying the answer to the simpler system
sometimes points out absurdities in the answer.

> One previous poster refused to discuss a single source system
> for some reason.

I fully agree. If the explanation works for the more complex system,
it should also work for the simpler.

> Since reactance disappears during DC steady-state, the relevance
> of a DC example is certainly questionable.

Perhaps, but we are dealing with simple circuit theory here using
ideal components. All seems to work.

> Hint: The Z0 of a piece of coax at DC is NOT 50 ohms.

I've seen nothing in the derivations for ideal transmission lines that
indicate frequency dependence. Care to elaborate?

In any case, if you wish to stay away from DC, we could just use an
arbitrarily low AC signal. How about 10**-100 Hertz? Indistinguishable
from DC for any engineering purpose? Or should we go lower? Just pick
the number.

You've still lost me. If the line loss is negligible when matched, even a high SWR won't increase loss appreciably. That is, in fact, why people use open wire line when the SWR is high. So I don't believe your 3 dB figure is correct. Where did it come from? How was it calculated?

Well, charge does seem to be key. Current is charge per time. Power
is voltage times current. I fail to understand the opposition to
using charge in the discussion. It is a basic element of circuit
theory.

This may be a challenge in optics but it is not at the lower AC
frequencies especially in a circuit. My power supplier does it all
the time. And sends me a bill to prove it.

Actually, I suspect that optics has more to learn from RF than vice
versa
since, with RF, one has the luxury of measuring both voltage and current
(and simultaneously at lower frequencies). Optics seems constrained to
pure average power measurements.

It appears that you are prepared to ignore Pinst = Vinst * Iinst. Could
you expand on when Pinst IS equal to Vinst * Iinst and when it isn't?

Simply convince me that Pinst is not always equal to Vinst * Iinst and
my difficultes will disappear.

p(t) = v(t) * i(t). Period. No phase, no vectors, no cross products.

You can't calculate instantaneous power from phasor quantities, because
phasors assume a frequency that's the same for all quantities, and the
frequency of the power wave is twice that of the voltage and current waves.

Of course, a lot of people mean "average power" when they say "power",
so you have to be very careful when reading anything written by those folks.

It is for the time it takes for the transient to die. Y'see, when you connect a battery to a transmission line, you don't have DC. You only have DC after you wait around forever or, for practical purposes, until everything settles to its final value within some small error bound.

It's also wise to remember that, likewise, when you connect a source to a line, you're not dealing with a single frequency. The system settles down to a single frequency only after all transients have died out. That's why a time domain analysis is necessary, or at least highly preferable, to analyze transient conditions.

But I do agree that, although it's instructive and can help understanding of transmission line phenomena, we have to be careful when extrapolating pulse or step results to sine wave situations -- especially steady state.

I agree that the quoted statement is incorrect, and should say rms instead of avg. And, strictly speaking, should say average power instead of just power. But the average value of a sine wave, assuming no DC offset, is zero, not 0.637 times the peak value.

Torque is the same as work. Work is energy conversion.

Meters cancel meters.

I recently saw somewhere on the web where a given light intensity was converted to the equivalent free space voltage and current. I think it was a response to Dr. Slicks inquiry over on sci.physics.electromag.

....yes, here it is.

> In which case, this would be equivalent to re-normalizing the
>Smith, and as you change the Z of both the PA and SWR meter,

When you talk about "the Z of the PA", you mean the output impedance.
When you talk about "the Z of the SWR meter", you mean the system
reference impedance Zo for which the meter is calibrated. These are two
completely different physical quantities. It is totally unrealistic to
talk about varying those two quantities together, keeping them
numerically equal like they were on some kind of twin-gang pot.

However, it's not completely beyond the reach of imagination, so let's
imagine for the sake of argument that somehow you could do it...

>you will
>absolutely measure a different SWR (you will measure the reflected
>power at point 2), going into 50 Ohms believe it or not.

Yes, you will indeed see varying values of |rho|/SWR on the meter - but
the point you're missing is this: although your imaginary experiment
involves varying two different values called "Z" at the same time, only
one of them is having any effect!

The changes you see on the meter are *entirely* due to what you're doing
to the meter itself - changing the Zo for which the meter is calibrated.
Changing the output Z of the PA is having *no* effect on the values of
|rho|. It never does.

You can easily demonstrate this in Real Life (tm) by doing what hams do every day - adjust the transmitter, which will change its output Z and its output power; but don't tinker with the calibration Zo of the meter (which is normally factory-adjusted for life). What you will find is that the "forward" and "reflected" readings change, but their ratio |rho| does not (within the limits of accuracy of the meter).

This is effectively the same experiment that I suggested this morning.

>Please get
>MIMP, it's a free program from Motorola.

Look, I've *written* programs like that, so I know exactly what's going on under the hood. What we're witnessing here is a demonstration that such programs can only give answers, not basic understanding. You have created some construct that seems to explain the program output for you; but it will not survive real-life experiments.

I find this most interesting. As a P.E. licensed by the state of Oregon (since 1981), I'm aware that I'm subject to state laws governing the code of conduct of Professional Engineers, and all other applicable state laws. I didn't realize that I had legal obligations to NIST, or that any other federal agency has requirements for P.E.s of all states. Would you please provide some reference where I can further research this obligation and the rules it has imposed that I'm legally required to comply with?

Greg,

thanks for the pointers. I have already used Google to do searches for information on this antenna, but some of your pages were new to me. I see that there is some software to design a HB9CV. This may be helpful in checking the antenna which I bought.

Instantaneous power is useless if an understanding is desired.
I agree with Hecht and all my other references. Kraus, Jasik,
Balanis, Hecht, Ramo & Whinnery all agree that dealing with
instantaneous power is a waste of time. Instantaneous power
is essentially meaningless since the definition of power
requires a length of time. There is simply no such thing as
instantaneous power. Power is always the energy passing a
point during a slot of time. Zero energy passes a point in
dt of time as delta-t approaches zero, by definition.

> Well, if you do a bit of fudging you can always make it work. But
> I do not observe these fudge terms in the expressions related to
> forward and reverse power in transmission lines.

Then you haven't read Dr. Best's QEX article. The interference is
there and takes the form of 2*Sqrt(P1)*Sqrt(P2) for 100% constructive
interference.

> Of circuit theory I have a reasonable grasp, optics I leave to others.

Too bad. The field of optics has already solved the problems with which
you are wrestling. Take a look at this web page to figure out how Z0-
matching works.

http://www.mellesgriot.com/products/optics/oc_2_1.htm

> As mentioned previously: stored in the line and moving back and
> forth between quarter wave boundaries.

Mentioned, but not explained. How does the energy's momentum change
direction in a constant Z0 environment? What causes the back and
forth movement?

> Back in basic circuit theory, some years ago, it was permitted to
> short points of equal voltage and open conductors with no current.
> Has this changed in the intervening years?

Ahhhh, I see your confusion. Circuit theory and transmission line
theory are not the same thing. Many have tried to mix the two
models and fallen on their faces. Transmission line theory is
simply more complicated than basic circuit theory. If you don't
believe it, replace a transmission line with ghosting with an

equivalent circuit - the ghosting disappears. Are they really
equivalent?

> Because the observed voltages and currents are the same. The circuit
> has been replaced by one which is indistinguishable from the first.

BS! I can certainly distinguish between a short and a non-shorted
transmission line. Please try again.

>>You have gone from 100%
>>transmission of waves to 100% reflection of waves.
>
> An intriguing assertion, but one which can not be demonstrated through
> any observations made on the circuit.

Of course it can by observing ghosting in a TV signal. With the line
shorted, there is no ghosting. With the line not shorted, there is
ghosting. Why is that so difficult to understand?

> I am not sure why you are looking so hard for reflections. I am not
> attempting to claim that there are any. I simply claim that no energy
> can cross the boundaries because the current or voltage is always 0.

In the real world, if no RF energy crosses a boundary, then that energy
is reflected since it cannot stand still. Of course, the supernatural
world is an entirely different matter.

> Basic electriciy. This says nothing about the presence or absence of
> reflections or whether there is a mechanism to prevent the energy
> crossing the boundary or it just happens through the dynamics of the
> distributed capacitance and inductance.

Unfortunately, this is beyond the ability of basic electricity to
handle. It takes the wave reflection model (or quantum physics) to
handle it. Einstein said a model should be as simple as possible,
but not too simple. Once again, you seem to be trying to force
reality to obey your model instead of vice versa.

> Oh, I fully understand what a 'directional watt' meter will indicate.

Then why are you so confused? :-)

> May I suggest that you perform the same experiment with a real
> instantaneous watt meter:

This is obviously a diversionary tactic. Instantaneous power is
essentially meaningless according to all my references and I
have a bunch of them. Would you care to provide a reference that
seriously deals with instantaneous power in transmission lines?

> I'm sorry, I do not grasp what you are attempting to say here.

That's more than obvious.

A number of texts, in presenting analyses that enhance understanding, use both instantaneous power and the instantaneous value of the Poynting vector as part of the explanation. Perhaps you mean that it adds unwelcome complexity to your simplified analysis?

> I agree with Hecht and all my other references. Kraus, Jasik,

Instantaneous power is defined in the first half dozen books I pulled from my bookshelf. They were:

Physics: Weidner & Sells
Circuit analysis: Pearson & Maler
Network analysis: Van Valkenburg ("Power, instantaneous" is even indexed)
Electromagnetics: Johnk, Holt, Kraus

You certainly have a lot to straighten us out on in your forthcoming paper!

Power is always the energy passing a
> point during a slot of time. Zero energy passes a point in
> dt of time as delta-t approaches zero, by definition.

By exactly the same reasoning, instantaneous current can't exist, since it has the same relationship to charge as power does to energy. By your argument, we should all through away that "useless" and "boring" analysis using time-varying currents, and deal only with average currents. The new math indeed.

Source record: 110236

The issue of the max. value of the magnitude of the reflection coefficient came up in our student mess. It was shown in lab that it must approach the square root of 5, which is close to 2.41.

But what is all of the noise about reflection coefficient (or SWR), which measures what is happening down stream, having anything at all to do with what is happening up stream. Wow. I have never had a student who was that illogical. However, if I were to encounter such a person at this time of life, I would suggest a career in politics or the UN. My hat is off to those of you who are succeeding in educating the lurkers. I marvel at your restraint towards others.

I was mostly responding to your indication that optics had less capable
measurements techniques available. Less measurements typically implies
less understanding.

> > It appears that you are prepared to ignore Pinst = Vinst * Iinst.
>
> I will go with all my references - instantaneous power is essentially
> useless for any kind of serious analysis.

It may be useless for serious analysis, yet violating
Pinst = Vinst * Iinst would seem to draw a lot of electrical engineering
into question.

It does go back to 'double think' unless you can explain how energy
can flow when the power is zero.

> Average power is the only thing
> that matters at RF and optical frequencies. Please provide a transmission
> line reference that extols the virtues of instantaneous RF power.

While I do extol the virtues somewhat, my main concern is that the
expression describing it not be violated. See above.

So I will repeat the challenge:

"It appears that you are prepared to ignore Pinst = Vinst * Iinst. Could
you expand on when Pinst IS equal to Vinst * Iinst and when it isn't?

Simply convince me that Pinst is not always equal to Vinst * Iinst and
my difficultes will disappear."

One of the techniques for terminating a rhombic is to connect the terminating resistor to the rhombic via a buried transmission line. The loss on the buried line reduces the power requirements for the terminating resistor.

Don't know that I would be burying the line to the antenna. If you use a large enough conduit (dia greater than say 10 times the wire separation) and the line is supported centrally, and you ensure that it will remain dry, it might be acceptable - but somehow, I don't think that was what you had in mind.

3599. The two sorts of loss

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 00:53:43 UTC
From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <bhugqm$bm0$1@hercules.btinternet.com>
Source record: 110243

Please consider this to be written in red ink, or it may turn out to be my blood.

The interminable arguing about losses in transmitters, tuners, transmission lines, antennas, baluns, matching sections, ground systems, etc., never reach any conclusions because half the time the participants, without being aware of it, are are not talking about the same things. The internal impedance/resistance of the source appears in the arguments and then disappears of its own accord or somebody re-introduces it an attempt to prove a point and then finds it convenient to forget about it. Confusion reigns. Hackles rise. Blood pressure soars. Threats of Legal Action are made.

This is because hardly any of the participants have ever been aware there are two sorts of loss. Education has been neglected. Both can be described in terms of decibels or even S-units. The performance of given black box in a transmission system can be analysed in two different ways, each way usually having a different loss in terms of decibels but when assessing overall performance it is vital to understand which sort of losses are involved.

There are "Transmission Losses" and there are "Insertion Losses."

There will now be raised voices of protest - "This bloody Limey is insulting our intelligence again". "We have read books about Insertion Loss as recommended by our professors". Invitations to tea parties can be expected.

Transmission loss, of course, is that defined by the ratio (Pout) / (Pin) of a network or a single section of a network. Overall loss being the product of the ratios of individual sections. The transmitter's performance is usually unknown, it can be considered to be external to the system and omitted from an analysis.

Insertion loss applies to individual sections of a number of cascaded sections. It is the *change* in overall loss which results from inserting the individual section in a cascade. Numerically it is the difference in dBs between 'before' and 'after' the insertion.

Consider the tuner, an impedance-transforming network. It is clear the insertion loss of a correctly operating tuner is in fact a *Gain* and differs considerably in dBs from overall system loss before it was inserted.

There is an excellent small book which I once read "Transmission Line Transformers" (baluns wound on ferrite cores), which contains many transformer measurements of loss versus frequency. The author states explicitly all measurements are in terms of the loss when a transformer is

inserted between specified generator and load impedances. I venture to guess not a single amateur has ever considered the additional (transmission) loss due such a transformer which may occur when both the generator and terminating impedances are unknown or at least are considerably different from the standard resistances between which the transformer has been designed.

The moral is - don't mix the two sorts of loss when trying to analyse how a transmission system works. Don't use insertion loss formulae anywhere in a system when the transmitter's internal impedance is not known. To use Scattering Matrix and circulator parameters, intended to simplify calculations at UHF and microwaves, is asking for trouble and disagreement. As has been amply demonstrated.

On the other hand, mention of transmitter internal impedance may force an analysis into considering the insertion loss of the feedline which I'm sure would not be welcome. If anybody knows what it is for rice-cakes don't tell anybody.

Total loss = 10*log((a^2-|rho|^2)/(a(1 - |rho|^2))

ARRL Antenna 18th edition, Chapter 24, Equation 15

Where: a = matched line loss = assumed 1
rho = 0.8181 reflection coefficient for VSWR = 10

+ + +

OOOPPPSSS!!! Math error!

Reviewing my calculations I made a major math error!! Glad I kept the work sheet.

In the numerator I used rho^2 not (1 - rho^2).

Now I am glad I retired from Engineering. :-)

Thanks again Roy!!

Conclusion, after I failed my ALGEBRA course, <sheepish grin>, the additional loss is zero within the stated assumptions. Which just proves I made 'Much ado about Nothing'.

Deacon Dave, W1MCE

I'll say three Hail Mary's and three Our Father's, assuming I can still count to three!!

Hi Tom, Thanks for your message. I have since borrowed a homebrew loop for camparisons with my trap vertical. (I had to take my trap dipole down) Well to put it straight I am amazed that a small 36" dia transmitting loop on 40 metres works every bit as good as my trapped vertical and with half the noise level. I can actually hear the stations. They give me good reports and when I switch to the vertical closer contacts give weaker reports but on DX they both seem the same. This is with the loop 10 feet high off the ground. Hope that is of interestto you....73 de Peter VK2EVB a loop convert.

==========

You don't need a lab. All you need is a pencil and the back of a cigarette packet.

Theoretical Max possible value = 1+Sqrt(2) exactly = 2.4142136 . . . . .

Can't imagine where you get 5 from.

It occurs when line Zo = Ro - jXo has an angle of -45 degrees, ie., when Xo = -Ro, and when the line is terminated in an inductive reactance of +jXo.

Reg.

The reference calls quantity "a" the "matched line loss ratio", and a value of 1 means no loss.

Does this mean that you are calculating the line loss in a lossless line?

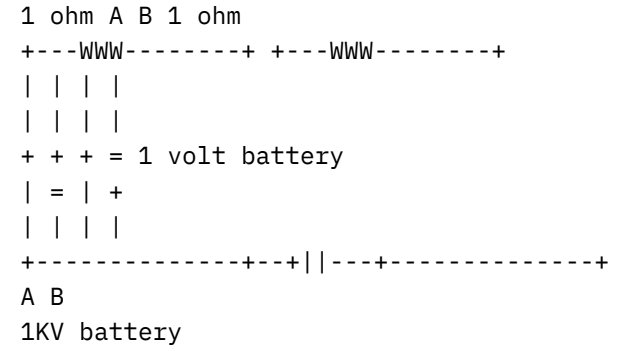
Interesting question, isn't it? It seems to me that this is a class
of problem that is succeptable to solution by several approaches,
classical network theory, or transmission line theory and perhaps
others. Identifying the solution that best matches physically
observable phenominia isn't always obvious. Applying Ockham's Razor
(spell it any of the alternative ways you wish) one might prefer the
simpilist theory that produces correct results.

But, to some extent the artifical conditions necessary in such a
statement are responsible for some of difficulty. I = E/R but as as
you make R zero, you have introduced a singularity into Ohm's law, so
in some sense I isn't determinable. There is also a finite propagation
time for current flow across the resistor, (and through the battery,

for that matter) and that might argue for a transmission line solution.

It also reminds me a bit of the question posed in electromagnetic theory class. You've probably seen it before as well. You have two wires going through the room you are in. With a clamp-on ammeter, you measure 1 amp in each wire, in opposite directions. With a volt meter, you measure 1,000 volts between the two wires. When asked to calculate the power flow, you answer 1,000 watts, being 1KV * 1A.

However, the actual circuit is 4 wires, and you only see two in the room. Two loops of 1 volt batteries with a 1 ohm series resistance, with the two loops bridged via a 1KV source. No current flow from the 1 KV battery and the total power is 2 watts, being 1 watt in each loop. As I recall, the only way to get the correct answer is to properly determine the Poynting vector, but it's damn near 40 years since I looked at it.



You can only see the wires at A-A and B-B.

It will work even better on 20m if you can reduce the value of the tuner capacitor.

If you havn't yet downloaded magloop design program MAGLOOP4 from website below you will find it very interesting.

As it happens, you've caught me right in the midst of trying to program just that calculation. But it turns out to be a toughie. It involves a couple of Bessel functions -- which aren't a problem in themselves, but the problem is that when the tube diameter is >>> the skin depth, the formulas I've come across so far require subtracting two huge numbers of limited accuracy (even if the wall itself isn't particularly thick in terms of skin depth). So the results I've gotten so far, even with double precision math, are garbage. I've been working at reducing and rearranging the equations, and using asymptotic approximations, but so far no joy.

Anyway, I believe the phenomenon you mention. I've come across it a couple of places. A similar thing happens with the plating of wires, where a relatively poorly conductive plating of the right thickness actually improves the RF conductivity of the wire. The effect, unfortunately, is quite small, as for the case of wall thickness.

I didn't think so.

> >>Hint: The Z0 of a piece of coax at DC is NOT 50 ohms.
> >
> > I've seen nothing in the derivations for ideal transmission lines that
> > indicate frequency dependence. Care to elaborate?
>
> You have got to be kidding. At DC, a piece of coax is just two wires.

I will take this as your agreement that Z0 is the same at DC since there
are no frequency dependent terms in the derivation of Z0. After all,
the distributed capacitance and inductance remain the same and they
store
distributed energy at DC just as the do for AC. They are not JUST pieces
of wire.

I find it difficult to understand the reluctance to study the
behaviour of the line for DC. You would typically do this DC analysis
by applying a step function to the line. Depending on the source and
load impedences the line may reach steady state quickly or it may
take forever. The reflection co-efficients all work perfectly for
analyzing the reflections during settling and once the line has
settled, the forward and reverse voltages and currents are present and
can be summed just as for the AC case. The line is storing energy
just as it did for the AC case. Everything works.

Why the resistance to examining this case?

Why the search for excuses so that one need not examine the case?

Are the insights offerred that uncomfortable?

Hi Keith,

Lets just observe a simple, real situation that any Ham may be faced with during a power black-out, or during Field Day. Take for instance a generator. It can give you 1KW of power. You need a gas powered engine to turn the generator. How much horsepower do you need?

The common exchange is 746W per HP for 100% efficient transformation. Thus you need at least 1.34 HP to obtain that kilowatt. What is a horsepower (certainly one of the most ancient of units) compared to these Watts (a relatively modern unit by comparison)? Is there a direct correlation between the power of a horse, and the power of a generator? Yes.

First, a word about multiplication by identities. An identity may also be known in this forum as a conversion factor. One such simple example is time conversion from seconds to minutes and back through:
(1 ï¿½ minute) = (60 ï¿½ second)
the identity is a simple division by one side or the other to leave 1.
A division by minute is a possibility for one identity:
1 = (60 ï¿½ second) / (1 ï¿½ minute)
equally valid would be to divide both original sides by (60 ï¿½ second):
(1 ï¿½ minute) / (60 ï¿½ second) = 1
you can confirm there is no hanky-panky by observing the common expectation that both sides of the equation describe the same thing, thus the identity of (1) over (1) equals 1 --- both times. In other words, the identity describes the same thing by different terms, and those terms are combined to offer a value of 1 (dimensionless).

The process of employing multiplication by 1 (performed below) through the use of identities with the time example described above (meaning you have converted to a form of x = 1 or 1 = x) allows for us to combine and clear terms in shifting from one basis of measurement to another.

To return to our query about the generator and the engine,
1 Horsepower is 33,000 ft-lb/minute. In the old days, a horse had to pull against a known load for a know period of time over a known distance to arrive at this common reference. The popular definition will allow you to see these units already in place:
33,000 ï¿½ foot ï¿½ pound / minute

We begin our trip towards the S of MKS through Units conversions, by casting out minutes with the time identity multiplying this value:
33,000 ï¿½ (foot ï¿½ pound / minute) ï¿½ (1 ï¿½ minute) / (60 ï¿½ s)

Clearing those terms leaves us with:
33,000 ï¿½ foot ï¿½ pound / (60 ï¿½ s)
or
550 ï¿½ foot ï¿½ pound / s
when the minute terms are canceled and the equation has been corrected to using seconds. [I hope many recognize this alternative conversion factor. It proves that nothing is lost through these conversions.]

Next we move toward the K of MKS by casting out pounds:
550 ï¿½ (foot ï¿½ pound / s) ï¿½ (1 ï¿½ kg / 2.205 ï¿½ pound)
This would be tempting to perform, but it would be absolutely wrong! As far as the expression of power in the original statement goes, the identity of pounds and kilograms is incorrect. This is because kilograms express mass and pounds express weight, which is the product of mass times the acceleration due to gravity. The pounds do cancel in the equation above, but the statement is incomplete and should be:
550 ï¿½ (foot ï¿½ pound / s)
ï¿½ (1 ï¿½ kg / 2.205 ï¿½ pound)
ï¿½ (9.807 ï¿½ m / sï¿½)

Combining and casting out terms leaves us with:
2446 ï¿½ foot ï¿½ m ï¿½ kg / sï¿½

Finally, to complete the progress towards MKS, we move toward the M of MKS by casting out foot using the length identity:
2446 ï¿½ foot ï¿½ m ï¿½ kg / sï¿½ ï¿½ (0.3048 ï¿½ m) / (1 ï¿½ foot)

Combining and clearing terms leaves us with:
745.5 ï¿½ mï¿½ ï¿½ kg / sï¿½

THIS is the NIST definition for power, but as such it may be unfamiliar to many (certainly given the angst and denial that attends this discussion). For the comfort of many, we draw in another identity that comes closer to expectations.

That is the identity of Power (also in MKS terms) that reveals itself as joules per second, or newton-meters per second:
(1 ï¿½ Watt) = (1 ï¿½ kg ï¿½ m / sï¿½) ï¿½ (m) / (s)
or
(1 ï¿½ Watt) = (1 ï¿½ kg ï¿½ mï¿½ / sï¿½)
whose identity becomes
(1 ï¿½ Watt) / (1 ï¿½ kg ï¿½ mï¿½ / sï¿½) = 1

We apply this to the power equation above:
745.5 ï¿½ (mï¿½ ï¿½ kg / sï¿½) ï¿½ (Watt) / (kg ï¿½ mï¿½ / sï¿½)
which (guess what?) reduces to:
745.5 Watts

QED

Rounding introduced 0.5 Watt error (the values provided by NIST to their complete precision would eliminate that). It also confirms what we already knew, but few could prove with a linear exercise like this. That's not uncommon however, because few deal with the Physics of the terms they are familiar with, this is the provence of the Metrologist and research scientists, not amateurs.

It is enough to say Watts and Horse Power exhibit a constant of proportionality, but it is wholly wrong to say that electrical Watts are somehow different from an animal's work expended over time.

It is equally in error to maintain that the resistance or Z of free space is somehow remote and different from the resistance of a carbon composition resistor or Radiation Resistance. ALL terms employed in the expression of permittivity and permeability conform to these same linear operations that prove they are congruent.

Well, slightly more. The capacitances and inductances are spatially
distributed. Should make the math a bit more complicated but hasn't
introduced anything new.

> If you don't
> believe it, replace a transmission line with ghosting with an

Well if the ghosting disappears, it was not the 'equivalent circuit'.
No surprises there.

> > has been replaced by one which is indistinguishable from the first.
>
> BS! I can certainly distinguish between a short and a non-shorted
> transmission line. Please try again.

Just to recap, the experiment was: a matched source connected to an open
transmission line. After the source is turned on (and a brief wait for
settling), measure any voltage or current you desire at any point on
the line. I short the points of zero voltage and cut the points with
zero current. You can now remeasure any current or voltage at any
points you choose to tell me whether the shorts or cuts are in or out.

Since you can not tell the difference, the circuit with cuts and opens
is identical to the one without.

We were, I thought, discussing an open transmission line, not one
carrying a TV signal. You have changed the experiment.

Oh, I don't think we need quantum physics to understand energy
distributions in ideal transmission lines. Let's not scare off
the neophytes.

> > instantaneous watt meter:
>
> This is obviously a diversionary tactic.

Not at all. A much better understanding will be had if both the
indications of real wattmeters and 'directional watt' meters are
understood. Limiting yourself to only one instrument limits the
opportunity for full understanding.

> Instantaneous power is
> essentially meaningless according to all my references and I
> have a bunch of them. Would you care to provide a reference that
> seriously deals with instantaneous power in transmission lines?

It's not so hard that you need a text book. V, I, cos(theta) and
a little thinking will suffice. Draw a sine wave for the voltage
and one for the current shifted by 90 degrees. Compute the
power (which will be a new sine wave at double the frequency).
Observe that the power goes positive and negative representing
forward and reverse energy flow. At any instance (at a single point)
the power is either positive or negative. Energy is either flowing
in one direction or the other at any given instance.
And remember that at any point where the voltage or current is

always 0, no energy is ever flowing.

Good day Richard,

You have picked an example that simply has different representations
for power. I do not believe there has been any dispute about whether
conversions between different units of power are valid; they are.

The general question is: if two things can be simplified to the same
set of units are they the same thing.

At least two counter examples have been offerred to demonstrate that
just because two things have the same units, they are not the same.

Torque is not work; though they both have N-m as their units.
Modulus of elasticity is not stress; though they are both expressed
as Pascals (after simplification).

This seems sufficient to prove that two things with the same units
are not necessarily the same.

It leaves open the question as to how does one know whether two
things with the same units are the same (or not); a much more
challenging problem, I suspect.

...Keith

"Consider the tuner, an impedance-transforming network. It is clear that the insertion loss of a correctly operating tuner is in fact a "Gain" and differs considerably in dBs from overall system loss before it was installed."

It`s early morning in England so Reg is likely snoozing. He probably wanted to instigate before turning in. I`ll bite. The decibel (dB) expresses gain, loss, and relative power levels. Its logarithmic character allows addition and subtraction to keep track of system gains and losses.

An amplifier can increase power so it can be a +dB insertion in a system. The amplifier is an active device. A tramsformer can change volts and amps by transformation of impedance (V/I), or the transformer can give isolation between circuits.Because the transformer is a passive device, it can`t be a +dB insertion in a system. It must be a -dB insertion in a system despite a "voltage gain" in some cases. A good transformer usually is very efficient, so its power loss is small, but it`s still a loss. The same is usually true of an antenna tuner.

Best regards, Richard Harrison, KB5WZI

Dear Reg:
Lab equipment was not used. The lab was just a convenient gathering
place with a blackboard. (No cigarettes in our lab or anywhere inside
buildings.)
I suspect that we made an arithmetic error. Need to revisit what we
did - much too late at night right now.
Thanks for the poke. 73 Mac N8TT

Yes. The value of any undistorted sine wave which is symmetrical about the zero axis is zero over one complete cycle.

0.637 and 0.707 are half-cycle values which are quoted as the average and rms fractions of the peak value of a sine wave in references containing such trivia. I just remember tthat the average in this case is about 0.9x the rms value.

Goodness, didn't you do this at Texas A & M? Or did they just give you the formula for average power and tell you to forget the rest? But the calculation that follows requires only high school level trigonometry, not engineering mathematics.

v = 100 cos(wt)
i = 2 cos(wt + 90)

v * i = 200 cos(wt)cos(wt + 90)
= 100 cos(-90) + 100 cos(2wt + 90)
= 100 cos(2wt + 90).

What you have here is a sinusoidal waveform of radian frequency 2w, centered about zero. Cos(90) is zero. The result above, the power, or rate of energy transfer, is not zero. It shows that energy moves back and forth at twice the rate of v and i, and that the same amount that moves one way moves back on the alternating cycle.

Richard, perhaps the notion is that use of the tuner increases the power actually delivered to the antenna compared to what would have been delivered in its absence. This is sometimes referred to as reflection gain and results from the presence of more power in the load than the absence of the tuner would permit.

In itself, it the tuner has I^2R losses to be sure, but if the antenna radiates 100 watts with the lossy tuner in place and only 20 watts without it, how wrong it is to claim an insertion gain of 80 watts for the tuner?

This is a common theme in the notion of conjugate matching in which mismatch loss is compensated by reflection gain caused by appropriate tuner parameters, etc.

Again, words tend to mean what people expect them to mean and sometimes people don't agree on seemingly common words like gain and loss.

Keith wrote:
"It does go back to "double think" unless you can explain how energy can flow when power is zero."

Think! The only way the voltage can go to zero on a good transmission line which is energized is by interference between an incident wave and a reflected wave. Zero volts on the line is merely a manifestation of VSWR.

Forward (incident) power and reverse (reflected) power are both on the line. A zero voltage on the line requires a complete load reflection so that the reflection volts are as strong as the forward volts.

A directional coupler, at the very spot where a slotted line probe would sense zero volts, would show you have full power (with its volts and amps) coming and going.

In reality there is not zero volts in the incident wave or in the reflected wave. There`s full voltage coming and going. The volts just happen to be out-of-phase at this point.

Best regards, Richard Harrison, KB5WZI

3633. 32 FT VERTICAL -- counterpoise length??

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 05:46:54 UTC
From: antennas@yahoo.com
Message-ID: <e8be44e3.0308192146.7b80aa52@posting.google.com>
Source record: 110176

I have an old Shakespear 32 ft antenna. Fed at side near bottom and a large bottom plate. Want to know if I mount it up at the top of a mast how long should I make radial wires for? Do I just calculate for lowest freq and make them 1/8 wavelength? I am going to run it through my tuner to get as many bands out of it as I can. Only about 40ft of coax so it is not too long.
Or should I try and design my own trap vertical of some sort??
Thanks.
Andrew VE8AE

Your point it well taken, but cancellation of units has always worked for me, and everyone else i went to college and high school with.

And I admit that a wave traveling in a transmission line is different from an EM wave traveling through space. All i'm saying is that the E field is defined by a voltage potential field, and the H field by amperes, so to say that the E field has nothing to do with voltage potential is a wrong statement in my opinion. And it's still ohms for the impedance.

It's a difficult question, and i'm glad we are discussing it. All i'm saying is, the units have to be the same, where ever you use them.

Slick

If you take a solid axle, fix it at one end and twist at the other, Torque is the plastic deformation in the form of that twist being distributed along the length of the axle as shearing stress. That twist allows for some rotation at the end where the rotational force is applied and that is obviously work. I know, I've calibrated 100's of Torque wrenches (mostly micrometer click wrenches) from 15 pound-in to a 600 pound-ft and broke a bench doing it.

>Modulus of elasticity is not stress; though they are both expressed
>as Pascals (after simplification).

This has a close association with your observation above, so I will continue with the same model. But first, the definitions that you seem to accept, but tied into this discussion. From "University Physics," Sears and Zemansky, containing a chapter called "Elasticity" whose second section is titled "Stress" (the first section is titled "Introduction").

"Stress is a force per unit area."

"Strain. ...refers to the relative change in dimensions ... subjected to stress." As this is distance over distance, strain has no dimension (the units cancel as has been pointed out by others).

"Elastic modulus. The ratio of a stress to the corresponding strain is called an elastic modulus. ... Since a strain is a pure number, the units of Young's modulus are the same as those of stress, namely, force per unit area. Tabulated values are usually in lb/inï¿½ or dynes/cmï¿½."

Returning to that same axle. We score a line along its length from free end to fixed end with a scribe that travels a path parallel to

the axis. We apply some force, hold it, and scribe a second line. We go to the middle of its length and scribe two lines around the circumference of the axle (a short distance apart). These last two lines describe opposite shears due to torsion. The stress varies as a function of depth into the axle (greater at the periphery, less in the interior). We then examine the enclosed area which describes a twist per length (area for the applied force - stress). The axial lines are parallel to the compression and the circumferential lines are parallel to the tension. If this axle were made of wood, it would fail under compression when its elasticity was pushed beyond its limit. In comparison, it would also exhibit a larger rotational displacement with the same force applied to an iron axle.

The last observation is simply reduced, or normalized as described above in the definition of modulus and what you obtain for the two materials is either a constant force with different rotational displacements (and different scribed areas); or the same rotational displacement (constant scribed areas) with different applied forces. You still have torsion, you still have stress and strain, and you still have rotational displacement - the only difference is in the material's characteristic which is described by the modulus.

>
>This seems sufficient to prove that two things with the same units

It proves you have two different materials which is the point of a modulus in any discipline.

>

>
>...Keith

Hi Keith,

The only question is what is different, the why follows from fairly obvious implications of being material based. Your problem is in the definition of the application of the terms, not their expressions. You might want to consult a slim volume called
"Elements of Strength of Materials," Timoshenko.

You will note that this bears no relation to ohms being different, because as you observed with the horsepower example, it is simply flipping through translations until you hit the units you want.

Nope. you are just changing where the reflections actually happen,
either before or after the SWR meter. In one case you measure it, in
another you don't. As simple as that.

If you still think there is a cabal, then you missed the whole point.

If you thought it was a personal attack against Reg, then you completely misunderstood my motives in writing all that. (And anyway, Reg probably regards "audacity" as the highest of compliments :-)

And if you thought any of it was written in anger, then you never understood a single word.

No, it's even simpler. A good SWR meter only *senses* the conditions on
the line - it does not significantly disturb them. You seem to believe
that calibrating an SWR meter for a different Zo "changes where the
reflections actually happen" - it doesn't have to, and if at all
possible it should avoid doing so.

You're now going to claim that an SWR meter contains a section of
transmission line. In such cases you'd be right about the reflections,
but that is a feature of one particular type of meter, and one
particular type of construction - it isn't a fundamental requirement. As
a counter-example, the Bruene bridge meter is not based on a
transmission line, can be made as physically small and non-intrusive as
technology allows, and can be re-calibrated to any Zo by simply tweaking
a capacitor or a pot.

To repeat: a good SWR meter senses only the impedance at its *output*.
And the source impedance has no effect on the readings of |rho| or SWR.

Oh come on, did you really imagine I was lying?

www.ifwtech.co.uk/g3sek/netcalc.htm
www.marsport.demon.co.uk/scalc.htm
www.marsport.demon.co.uk/sekpmk.htm

These are the ones that come immediately to mind that involve impedance operations (there are also many others, in other areas). NETcalc is entirely mine; Scalc is a collaboration; and the programs in the BASIC software collection are sometimes mine, sometimes improved versions of very ancient programs by other people. Even when someone else wrote the original code, I've been 'under the hood' and take technical responsibility for every line.

NETCALC in particular is a 'Swiss Army Knife' calculator for complex impedances, which I wrote almost 20 years ago because I needed one. There still isn't anything else that does quite the same job. It includes Z0 transformations, and impedance transformation by loss-less transmission lines, but it doesn't include line losses (never got around to it) or complex Z0 (something I learned about here, from Reg). However, if anyone wants to upgrade it...

The BASIC source code for all the programs is there to download (except Scalc). Some of it isn't elegant, and all of it shows its age, but its age also ensures that there aren't many technical errors - these programs have been around for long enough to have been thoroughly debugged by large numbers of users.

We haven't been maintaining these programs much in recent years, as others like Reg and VE3ERP are now filling the small BASIC/DOS program niche very well.

> >
>
> Actually, thats 2*pi*radius*force*moment arm. Right.

In my example, I intended the 'radius' to be the radius at which the
force was applied so the 'moment arm' was already accounted for. When
the radius is the radius at which the force is applied, 2*pi*radius
is the distance through which the force has acted after one revolution
so the expression is the same as the common force*distance used for
linear work. More generally, it does not matter what the shape of the
path is; the work is always the force times the distance along the path.

> VSWR.

No disagreement from me as long as you replace 'incident wave' and
'reflected wave' with the more precise 'incident voltage wave' and
'reflected voltage wave'. This aligns with the precise use of V in
VSWR.

Adopting Roy's more precise notation for power
P(t) = V(t) * I(t) (1)
The question is: Do you accept this expression as describing power?

a) If not, then there is no "double think", but a lot of electrical
engineering will have to be tossed as well.

b) If you do accept (1), then in a case where V(t) is zero for all time,
power must be zero as well. V(t) is zero for all time at a current
maximum in a shorted transmission line, so the power (energy flowing)
must be zero as well.

c) If you accept (1), but also claim that there is energy flowing when
V(t) is zero, then "double think" is an appropriate description.

I think these are the only 3 options.

If you choose b), then I think we are in agreement.
If you choose c), then ... I'm not sure what the 'then' is.
If you choose a), we can explore all the difficulties that will arise
when (1) is not true and with some effort you may arrive at b).

> Forward (incident) power and reverse (reflected) power are both on the
> line. A zero voltage on the line requires a complete load reflection so
> that the reflection volts are as strong as the forward volts.

The sentence with 'volts' is correct. The sentence with 'power' leads
to a great deal of difficulty as described above.

> A directional coupler, at the very spot where a slotted line probe would
> sense zero volts, would show you have full power (with its volts and

> amps) coming and going.

Many people use directional couplers as a reason to stay out of
camp b), but this necessarily means they are in a) or c). The first
step to enlightenment is to briefly set aside directional couplers
and 'Bird watt' meters, and realize that in a choice between a), b)
or c), b) is the only place it makes sense to be. Then go back and
figure out how directional couplers are not inconsistent with b).

> In reality there is not zero volts in the incident wave or in the
> reflected wave. There`s full voltage coming and going. The volts just
> happen to be out-of-phase at this point.

Yes, indeed. But there is no power.

You must have misread the question. Shorts are only applied at points
with zero volts and only wires with zero current are cut. Since there
is no 'signal' present at these points, the 'signal' will not disappear.

For your convenience, I have provided the experiment again, below.

"Just to recap, the experiment was: a matched source connected to an
open
transmission line. After the source is turned on (and a brief wait for
settling), measure any voltage or current you desire at any point on
the line. I short the points of zero voltage and cut the points with
zero current. You can now remeasure any current or voltage at any
points you choose to tell me whether the shorts or cuts are in or out.

Since you can not tell the difference, the circuit with cuts and opens
is identical to the one without."

This message concerns an antenna used for EMC measurements but I am sure you will be able to reply.

We are setting up an EMC testing laboratory, one of the (very impressive!) antennas that will be used is a "Stacked Logarithmic-Periodic Test-Antenna", the details of which are in http://www.schwarzbeck.de/k9128e.pdf.

The antenna has been assembled, but the elements were not placed as in the photo (see pdf). Let me try to explain:

The elements were not placed diagonally opposite, as I imagine is required. (If the uppermost longest element is on the right, the next lower longest element should be on the left, as far as I can understand.)

I imagine that this will affect the directional 'balance' of the antenna, although I have no prior knowledge of EMC testing, just a basic understanding of antenna theory.

3647. Grounding question - this is wierd.....

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 12:30:32 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <e5qdnXr1IYR09N6iU-KYvA@comcast.com>
Source record: 110191

I'm trying to understand a grounding situation at myt ststion. Here is the station layout:

Pyramid Phase III 25 amp power supply feeding power to all devices. First there is the radio - a Yaesu FT817. The antenna output from this goes to a 2 position antenna switch. One side of the switch feeds directly to a high perormance 2m/440 dual band mag mount antenna on my A/C unit. The other side goes to a MFJ 1040B rf preselector (also powered by the Pyramid). The preselector has 2 antenna outputs - one goes to a Rat shack 11 meter "high performance" mag mount antenna (tuned for 10m) also on my A/C unit. The other output goes to a LDG Z11 autotuner. The output from the tuner goes to a 34' long inverted V antenna outside my window (I'm on the 3rd floor).

All these devices share a common ground through either the coax shield or DC power ground or both. I have yet to install a proper station ground for the whole setup and I don't know if the power supply is grounded properly at the 115v ac outlet.

There - now that that is said, here is the problem:

When tuned on any band, my SWR gets better if I touch the case of the tuner. I then installed a 1/4" braid from the tuner's chassis screw to the ground lug on the antenna switch and that solved the problem. I moved the braid from the antenna switch to the case of the MFJ 1040B and the same thing happened but not nearly as good as the effect I got when hooked to the antenna switch.

I thought the coax sheild was a good ground path - how could installing a ground line between the tuner and the switch help? All chassis's are metal except for the sides of the MFJ 1040B preselector. All patch coax cables have been swapped out with others with no changes seen. The system as a whole seems to operate well - on 10 m the mag mount works best. Below that the inverted V works better. Although the Z11 can't autotune below 5 mhz, I can manually tune and get a good SWR down to 1.8 mhz with the Z11 in manual mode.

Grounding will be easy when I get around to it - I have baseboard hot water radiators that I can ground to.

Any ideas, folks?

K4WGE wrote:
"The EM wave`s propagation speed is infinite at the center of radiation, (center of radiating antenna) and gradually decreases into speed of c at the end of near field."

Velocity = frequency x wavelength.

The product, frequency x wavelength must be infinite if velocity is infinite.

Directors and reflectors in parasitic antenna arrays exhibit phase (time) delays which depend on element spacings and these spacings are likely within the near field. I`ve never heard of any velocity corrections to the phasing required by near field immersion.

I`m missing something here.

Keith wrote:
"Why the resistance to explaining this case?"

Because it should be obvious to anyone who knows enough to ask the question.

Nevertheless, I assume the questioner is sincere so here is a simple answer. It`s in Terman if you want more details.

Zo = sq rt Z/Y

Z = R + j omega L = line series impedance per unit length, ohms.

Y = G + j omega C = line shunt admittance per unit length, ohms.

For r-f in good lines, this reduces to:

Zo = sq rt L/C

For d-c, this reduces to:

Zo = sq rt R/G

Obviously line immpedance at d-c is likely quite different from line impedance at r-f.

Best regards, Richard Harrison, KB5WZI

Hi Ken:

Sound to me like a classic RF in the shack problem. With the two mag-mount antenna that close to the rest of the station RF pick up seems like a sure thing. When you move your bit of ground braid around your changing the electrical length outside of the coax. Any wire over a few inches long is not a RF ground.

Keith wrote:
"Yes, indeed. But there is no power."

Keith`s perception is flawed. He is addressing r-f with a d-c mindset. R-F power flow does not stop at an SWR zero-voltage point. Like "Old Man River" it just keeps rolling along.

The zero-voltage point exists because the phase relationship between two oppositely traveling waves is fixed, and the zero-volts point is where the vectors cancel.

You must simultaneously sense both waves to find a zero. Sensing either wave alone finds no dip in voltage. Carramba!

Best regards, Richard Harrison, KB5WZI

"Since you can not tell the difference, the circuit with cuts and opens
is identical to one without."

There he goes again!

If you short an r-f transmission line where SWR has produced zero volts,
you make a difference. You change the reflection point to the short you
impose from its former location.

Best regards, Richard Harrison, KB5WZI

>
> For d-c, this reduces to:
>
> Zo = sq rt R/G

But we were discussing ideal lines, for which, if I recall correctly,
R and G are both 0.

This leaves us with Z0 = jwL/jwC (w being my font challenged excuse
for Omega)
which should, in the limit as w approaches 0, leave us with the same
answer as for RF. Or have I forgotten how to do math (which is quite
possible).

In any case, a slight modification to the experiment can get around
this difficulty. We'll just perform the experiment at a frequency
sufficiently low as to be indistinguishable from 0 given the duration
of the experiment.

> Obviously line immpedance at d-c is likely quite different from line
> impedance at r-f.

This would certainly be true for real world lines where the luxury of
R=G=0 does not exist.

Ian, G3SEK wrote:
"You are now going to claim that an SWR meter contains a section of transmission line."

At VHF where the wattmeter may affect SWR, it is customary to make the meter plus its cable extension into 1/2-wave so that its insertion and removal nave minimum effect.

It follows from the "logic" previously presented that if there are light rings and dark rings existing in a light interference pattern, The light ring energy is trapped between the dark rings which is well known to be a false assumption. All that happens at a voltage node on a line with reflections is simple wave interference between two waves. If the voltage is zero it is because of 100% destructive interference between two voltage waves. It happens all the time in optics and no optics engineer would be silly enough to assert that the bright ring energy is trapped and circulating between the dark rings.

> River" it just keeps rolling along.

P(t) = V(t) * I(t) is much more general than DC or sinusoidal RF. It
works
for any signal shape you choose, even non-repetitive ones.

It certainly works for my electic company who integrate P(t) and
regularly send me a bill.

> The zero-voltage point exists because the phase relationship between two
> oppositely traveling waves is fixed, and the zero-volts point is where
> the vectors cancel.
>
> You must simultaneously sense both waves to find a zero. Sensing either
> wave alone finds no dip in voltage. Carramba!

From this response it is clear that you are not yet in group b).

But is it:
group a) P(t) is not always equal to V(t) * I(t); or
group c) energy can flow when P(t) is a constant 0
?

Or maybe my list is incomplete and there is a 4th option which I missed.

May I respectfully suggest that if you are having difficulty selecting
which option applies to your thinking (and yet can't produce a fourth
option), that you try to discover the source of your discomfort. From
there, enlightenment may arise.

For myself, I recognized the "double think" and so rejected c).
P(t) = V(t) * I(t) seemed so fundamental that it had to be accepted
thus I was forced to reject a).
This left only b). Although it rejects some of the often stated and
accepted explanations about transmission lines, it was the lesser
of the evils. Some thinking revealed the weaknesses in the 'often
stated and accepted' explanations and now all is consistent.

This process took some time, prompted and assisted by the never ending arguments which go on in this group. So I do thank those mis-guided souls who argue endlessly and the patient answerers who respond mostly for the benefit of the lurker.

But be that as it may, do try and figure out whether option a), b) or c) best describes your thinking. Only an increased understanding can arise.

Let me see if I have this straight. You cut off 1/4WL of feedline and
current and voltage still exist in the cut off parts? Have you patented
that perpetual motion machine? All I have to do to prove you wrong is
measure the current and voltage in the part that was isolated from the
source. In the previous example:

```
1/4WL coax
source---------coax--------------------+---wattmeter-----short
```

When you cut the line at '+', the wattmeter will go to zero. It's
a no brainer. What do you mean I can't tell the difference?

> You can now remeasure any current or voltage at any
> points you choose to tell me whether the shorts or cuts are in or out.
>
> Since you can not tell the difference, the circuit with cuts and opens
> is identical to the one without."

But I can tell the difference because I choose to measure the current and
voltage in the parts of the feedline that have been cut off and isolated
from the source. It's a no brainer.

Using Keith's "logic", he would also be forced to assert that in a bright ring-dark ring light interference pattern, the energy in the bright rings is trapped between the dark rings and just sits there and circulates. That's one reason why the field of optics is so far ahead of RF transmission lines. Everyone in optics understands interference patterns which is exactly what RF standing waves are.

And all conditions on the "load" side change so the change is easily
detectable. The change can even be detected at the source by observing
the changing TV ghosting patterns. Keith's argument is just some primrose
path that takes us farther away from reality, not a very good goal, IMO.

George, W5YR wrote:
"This is some times referred to as reflection gain and results from the presence of more power in the load than absence of the tuner would permit."

Words work best when their meanings are agreed. It is generally agreed that the decibel (abreviated db) is a logarithmic unit used in communication work to express power ratios. (The definition is Terman`s.) The Bell System used the abreviation db, not dB.

An audio output transformer is used with a low-impedance speaker to better match a high-impedance source for a louder signal than the voice-coil in series with a tube would produce. Still, a good transformer is usually said to have low loss, not give more gain .

I have no problem with "reflection gain", but I would have looked for a definition.

Best regards, Richard Harrison, KB5WZI

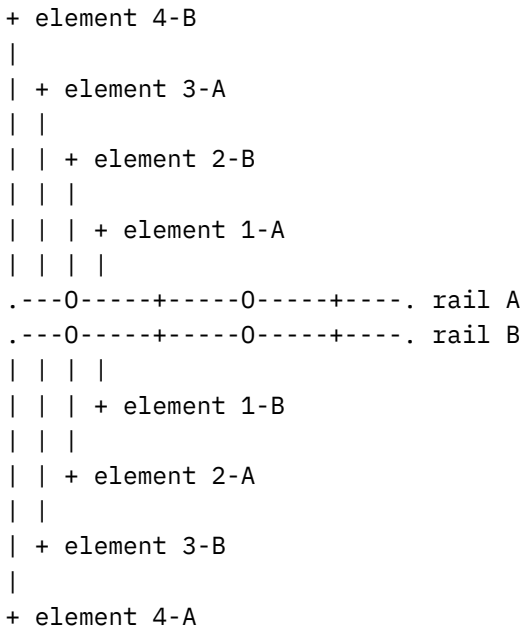
Description is vague at best. You are starting off with a presumption
that may be faulty as you infer.

>
>I imagine that this will affect the directional 'balance' of the
>antenna, although I have no prior knowledge of EMC testing, just a
>basic understanding of antenna theory.

Guessing aside, and taking a clue from this "diagonally" expression, I
would offer that you look at the antenna from above as you attempted
in your picture and see if it looks like:

```
+
|
| +
| |
| | +
| | |
| | | +
| | | |
.---+-----+-----+-----+----. two rails, one hidden by top
| | | |
| | | +
| | |
| | +
| |
| +
|
+
```

And confirm that each element, in order on one side, alternates
between the two rails that hold them. This is equivalent to:



Where the connections of elements denoted by "O" pass to the OTHER
rail. Both sides (common elements of any dipole pair) swap at each
step down the progression.

The luxury of R=G=0 does not exist anywhere in the known
universe. Your math model is predicated upon things that don't
(can't?) exist. Does that give you some sort of hint?

Seems to me this is just one more case of seduction by the
idealized steady-state model. "I think it, therefore it exists".

My mistake. I forgot to make clear that the transmission line was
ideal for this thought experiment; that is, R=G=0; no loss. The signal
does indeed continue to circulate for ever.

Please re-evaluate your answer after this clarification.

Power is the same as irradiance in optics. When total V=0, it is simply the result of destructive interference. Perhaps this quote from _Optics_, by Hecht, will enlighten you. "The principle of conservation of energy makes it clear that if there is constructive interference at one point, the "extra" energy at that location must have come from elsewhere. There must therefore be destructive interference somewhere else."

The voltage goes to zero because two voltage waves are engaged in destructive interference. The current goes to maximum because two current waves are engaged in constructive interference. The momentum in the voltage waves simply transfers to the current waves and they just keep on rolling along. There is no mechanism of physics existing at that point to change the momentum of the waves. Believing that no energy crosses a superposed V=0 boundary is just a wet dream. The current is at an absolute maximum point so plenty of charge carriers are crossing that boundary.

New ham antenna questions.... What would be a good antenna, store or homemade, for my vehicle? Where is the best place to locate the antenna on my vehicle?

I drive a Jeep Wrangler and will soon want to add a mobile with a dual band VHF/UHF antenna. This vehicle has two tops, one fabric and one fiberglass. I'm guessing I will probably attach the antenna to the light bar, the highest point on the vehicle, across the top of the windshield.

Thanks,

Ray

Given an ideal transmission line (necessary to achieve 0 volts), there
are no measurements you can make which will indicate whether the short
is present or not.

With the voltage and current distributions the same, with the standing
wave the same, it is not obvious that there is a difference when the
short is added or removed.

You have suggested that the reflection point has moved. But there are
no measurements which can show that this has occurred.
And yet, you argue that while the wave energy previously went through
it is now reflected. But nothing that you can observe on the line has
changed. Why are you so sure that the wave energy previously went
through this point of zero voltage?

Hi Cecil,

And you have yet to confirm it (or refute it) at the bench. Is your
interest more rhetorical than actual?

We engaged in a rather lengthy interchange to this topic, up to the
point of how you could evidence this for yourself. My methods and
data support your statement's sense. I offered only one proviso of
your rig being able to withstand the demands of such mismatch and you
offered your SGC could do that easily. As is stands left at that, the
remaining task should occupy no more than 10 Minutes of 16 readings
and note taking.

Actually, you've made the argument backwards.

If you explanations work only the complexities of the real world
but collapse in the simplicities of the ideal world, then you
should cast grave suspicions on your explanations.

Sorry if I seem a little dense here - but do you mean never as in using
the outer braid in an antenna line or using braid *made* from coax (like
the 1/4" flat braid I have)?

In other words, don't rely on the sheild to provide a ground path but
use a flat braid that is not part of an active transmission line?

My knowledge of optics is insufficient to comment on any analogies you
choose to draw. Fortunately, a knowledge of optics is unnecessary to
understand circuits and transmission lines.

> The voltage goes to zero because two voltage waves are engaged in destructive

This puts you in
group a) P(t) is not always equal to V(t) * I(t); or
group c) "double think".

Care to think about which and comment?

> The current
> is at an absolute maximum point so plenty of charge carriers are crossing that
> boundary.

Yes indeed, but current by itself is not energy. Remember
P(t) = V(t) * I(t) [unless you choose option a)]
Both volts and amps are simultaneously necessary for power.

So then that would be Work = 2*pi*(radius**2)*force.

Right. But it's a bit strange with rotational work, because if
you do one rotation, you are essentially back where you started. I
believe this has something to do with the fact that the rotational
displacement is dimensionless, and linear displacement is in units of
length.

Hi Ken,

Yes and no.

It has been offered, and your experience confirms, that there is RF on the coax (as well as RF "in" the coax). The solution is to inhibit that, not try to short it to ground. You can try, certainly, and succeed - for one band. Instead you should fix the problem by snubbing the current at the source. Use a choke.

The second part of using coax to ground components. If you have a wiring problem (you have one if you cannot trust your AC mains to supply ground) that lifts one chassis level to 115VAC and that is cured by a coax connection to another chassis safely at ground; then guess what happens when you hold that grounded chassis and disconnect the other's path to that ground? 115VAC through two arms and across the chest when you twist off the connection. That would not happen if they shared the same safety ground through proper connections.

I don't think anyone here is arguing that a wave traveling
through a transmission line is the same as an EM wave traveling
through free-space.

But as Richard has shown, the units are always the same, as they
should be. Just like a meter is still a meter, whether it is in
torque or work.

But it tells you something about what you are measuring, and the
clue is that the E field is defined by the voltage potential field,
and the H field by amps (turns).

And if the permittivity (impedance) of the material surrounding
an antenna will affect it's input impedance, i think it's something to
consider.

I'd appreciate any comments, pro and con, from actual users of the IC-706MKIIG. Performance, reliability, service problems, etc.

As it's described it seems to have features I'd like and need: small size, both HF and VHF, and a reasonable power level. Any suggestions as to other rigs with similar features would be appreciated also.

Hi Ray,

Welcome!

Ignore the antennas for a moment, and shop for mounting options
instead. The good antenna vendors have many to choose from and you
will spend more time with them than the antenna itself (which, if you
choose a good mounting system, you can then do home brew antennas to
mate to them far easier than re-inventing the wheel every time).

If it takes one newton to make a block move and I push it north 1 metre, then east 1 metre, then south 1 metre, then west 1 metre, I am back where I started but I did 4 joules worth of work (but probably not useful work).

If I push the same block in a circle of radius 1 metre then I do 2pi joules of work: the circumference (distance travelled) times the force.

So the expression at the top should not have a square in it.

>radiates 100 watts with the lossy tuner in place and only 20 watts without
>it, how wrong it is to claim an insertion gain of 80 watts for the tuner?

Very wrong!
Tuner is not attributing gain to nothing. It has losses due to losses in its components, doesn't matter how you slice it.
When you match antenna to transmitter output (especially solid state 50 ohm type) and make transmitter happy to produce full 100W output, you are not adding "gain" from/by the tuner.
That transmitter when looking to mismatched load cuts power back to 20W, when you insert tuner, you are not making up 80W in the tuner (gain?) but making transmitter produce full output. You are now putting 100W in and getting some 90W out, 10W lost in the tuner, but antenna is getting 90W from the combo.
Where is the gain in the tuner?
Looks like things are getting ridiculous here. No tuner (passive) has a gain, it has always loss.

I assume it's an unloaded fiberglass whip....Perfect for a 40m
antenna. If elevated, use 1/4 wave radials "appx 32-33 ft". Trim for
best match. You could feed it as a 5/8 on 17m with a small series
loading coil at the base. It should work ok on 15m, if you use the
tuner. The other bands, the feedline and tuner losses will vary. Just
try it and see. For any certain band used, you would prefer at least
one or more 1/4 wave radial. But 3/4 wave radials can work also. So
40m radials can double for 17 and 15 with decent results. If you try
to use with a tuner on bands where the match is lousy, I would prefer
a thicker low loss coax. So I would use rg-8/213, etc instead of
rg-58. Matched, the differece is very small, but I think it can
noticeably reduce losses a bit when you have a big mismatch. The
higher the freq, the more you would notice the difference. On the low
bands, it would hardly matter. You could feed it as a 1/2 wave on 20m
with very good results, IE: gamma loop feed, but that matching scheme
is going to be quite different than a 40/17 antenna. If you do this,
consider it a single band antenna for the most part. You would need to
pick one or the other. Hard to do all at the same time. Maybe use a
autotuner...But autotuners seem to be sort of lossy in such cases.
Also, if you use a loading coil, say for 17m use, it's best not to
ground the base. Just run it in series. You don't really want to dc
ground an antenna you are trying to run on all bands with a tuner, or
even dual band like the 40/17 combo. If you ground the coil, it will
ruin it on 40m. If you don't ground the coil, it just drops the
resonant freq on 40m a bit. I used a 24 volt relay to switch on one I
ran. MK

Richard is on the right track.

The coax braid in a transmission line is NEVER an INTENTIONAL ground. It may be at ground potential because it is connected to two chassis that are each grounded directly, but it is never the intentional ground connection. Because, as Richard points out, if one side is lifted then one of the two items item is now floating.

The USAF does not [NOT!!] advocate ground straps!! If you want something grounded then ground it through the chassis connection. Electrical returns, also, were always treated as isolated circuits. All returns were connected together and then only connected to ground at one point in the system, generally at the source.

I spent three years of an engineering career working as the integrating contractor on system level grounding and bonding diagrams for a major USAF Missile flight components.

A transmission line with perfectly real characteristic impedance doesn't exist.

And the (average) net power equals "forward power" - "reverse power" only if the transmission line has a perfectly real characteristic impedance. Yet you've often blandly subtracted the reverse from the forward to get the net power. Your math model is predicated upon things that don't (can't?) exist. Does that give you some sort of hint?

Egad, you've been seduced, too!

Most SWR meters i have opened up ARE transmission-line thrus, with
directional couplers.

And i've doubted that you can re-calibrate Zo by changing the
termination shunt resistor, as Cecil claimed. I mean, it must have
some sort of thru in it, and it must offer some sort of impedance
(discontinuity).

3692. Indoor Wireless Cable TV Transmission

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 18:28:16 UTC
From: randy@lilrandys.net
Message-ID: <771d42b1.0308201028.2c8b6015@posting.google.com>
Source record: 110136

I would like to have something plug into my cable tv jack that can transmit the cable over to another antenna that is plugged into the VHF input on the VCR in another room. That way I would not have to run cable from the cable jack in my bedroom to the home theater system in the living room.

Does anyone know of any items that would allow this? I think I need a tranmitter and a reciever, but I do not want to change channels at the transmitter - I want to be able to change with the reciever (plugged into the VCR).

Any ideas??

Thank you very much for your help and time!!

Actually, my first posting was right all along, if Zo is always
real.

From Les Besser's Applied RF Techniques:

For passive circuits, 0<=[rho]<=1,

And strictly speaking: Reflection Coefficient =
(Zl-Zo*)/(Zl-Zo)

Where * indicates
conjugate.

But most of the literature assumes that Zo is real, therefore
Zo*=Zo.

And then i looked at the trusty ARRL handbook, 1993, page 16-2,
and lo and behold, the reflection coefficient equation doesn't have a
term for line reactance, so both this book and Pozar have indeed
assumed that the Zo will be purely real.

That doesn't mean Zl cannot have reactance.

Try your calculation again, and you will see that you can never have a [rho] (magnitude of R.C.)greater than 1 for a passive network.

How could you get more power reflected than what you put in? If you guys can tell us, we could fix our power problems in CA!

But thanks for checking my work, and this is a subtle detail that is good to know.

>Andrew VE8AE

Hi Andrew,

I presume by "fed at side" that this is through some proprietary
matching - or is it simply insulated from ground?

Use a tuner and forget tuning the radials. You might be tempted to
build them to "formula" but given that they will no doubt be of the
drooping variety, then that is an entirely different game. As such,
add as many as you are comfortable with, as long as you can make them
without having to bury their tips (a good idea is that their lowest
point should be out of reach).

Be aware that as impressive as it may feel, the height may be a
detriment in the higher HF (too long and radiation will be skyward,
bound).

3697. A Subtle Detail of Reflection Coefficients (but important to know)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 18:47:30 UTC
From: radio913@aol.com
Message-ID: <1d15af91.0308201047.7dff6029@posting.google.com>
Source record: 110141

Actually, my first posting was right all along, if Zo is always real.

From Les Besser's Applied RF Techniques:

"For passive circuits, 0<=[rho]<=1,

And strictly speaking: Reflection Coefficient =
(Zload-Zo*)/(Zload-Zo)

Where * indicates
conjugate.

But most of the literature assumes that Zo is real, therefore
Zo*=Zo."

And then i looked at the trusty ARRL handbook, 1993, page 16-2,
and lo and behold, the reflection coefficient equation doesn't have a
term for line reactance, so both this book and Pozar have indeed
assumed that the Zo will be purely real.

That doesn't mean Zload cannot have reactance (be complex).

Try your calculation again, and you will see that you can never
have a [rho] (magnitude of R.C.)greater than 1 for a passive network.

How could you get more power reflected than what you put in (do
you believe in conservation of energy, or do you think you can make
energy out of nothing)? If you guys can tell us, we could fix our
power problems in CA!

But thanks for checking my work, and this is a subtle detail that
is good to know.

3699. Re: The two sorts of loss

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-20 18:49:10 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vk7gl2mgslh824@corp.supernews.com>
Source record: 110143

This is another example of the problems that can result from misunderstanding the term "mismatch loss". People have been talking about its reciprocal (or negative, in dB) here, and calling it "reflection gain", a term I hadn't heard before but I don't doubt the term is legitimate.

I've posted fairly extensively about "mismatch loss" on this newsgroup. You should be able to find the postings easily with a Google search. The main point is that "mismatch loss" (and its reciprocal "reflection gain") don't really represent loss in the dissipative sense, but rather "power that coulda been but ain't". It's a useful concept, but one just asking for misinterpretation and misuse by people who don't really understand what's happening. Hopefully a look at my previous postings will clarify the matter for you. Once you understand what "mismatch loss" really is, the concept of "mismatch gain", or "reflection gain" as it's being called, should be easy to comprehend.

Repeat of earlier post which failed to make it into the NG! Devoured by ISP
?

Hi folks
Although licensed for over 12 years, converting 3 years ago to a
M0...callsign (with 12 wpm cw), personal circumstances have not until now
permitted me to get started on HF.

Problem now is antennas (and indirectly xyl).

Would initially like to cover 14 - 7 and 3.5 MHz with a coax fed
horizontal wire dipole of approx 66', which if carefully cut would
theoretically give full - 1/2 and 1/4 wave respectively for these bands.
An MFJ-949E Atu is available.
Garden to rear of property, narrow but 80' long from house to boundary.
A further 25' is available along side of property, rear to front, but
approx 6' proximity to house wall.
Height of proposed feedpoint approx 17' 6" ; height at boundary 12'
No garden or roof space for any vertical metal!

That's the idea - but I would welcome constructive comment, especially in
the area of feedpoint impedances and swr.
Also would 450 ohm feeder be better than coax ?
My thanks in anticipation. . . .
Bert

Regrettably, due to shared facilities, I am unable to accept incoming
email, so posts to newsgroup pse. ##

Hi Bert,

You seem to have enough room (as long as the length is broadside to
the direction you want to transmit).

You will encounter Hi-Z at some point. Cut another dipole (half size)
to attach to the same drive point and hang its ends a foot below the
larger, original one you planned.

Remember to choke the feed point and you won't bother the household or
neighbors (as much).

I own one of them & also a Yaesu FT 857. I think with the combination of
the 857 & the ATAS 120 antenna my choice would definately go that way.
Charles

Deacon Dave wrote:
"So, which one is infinite?"

Yes. That was my question too.

A velocity change within the near field might produce a shrinking wavelength as the velocity slows. How far does the near field extend with an infinite wavelength?

I`ve heard of velocities greater than c, but these are relative. You have incident and reflected waves on a transmission line and their velocities, rekative to each other, usually exceed c. In space, c is so reliable, we use it to measure distance.

Can we now challenge the radar speed traps?

Best regards, Richard Harrison, KB5WZI

Well, the problem here is that the bandwidth of that coaxial cable coming out of the wall is probably on the order of 200-500MHz, depending on how many channels you cable TV provider gives you. You aren't going to find any reasonably priced device that'll transmit that much bandwidth wirelessly.

> Any ideas??

Hire some talented kid to run that cable for you for, say, $50-$100?

You might want to take a mozy around the exterior of your house and see where the TV cable is (I'm assuming your house wasn't originally built wired for cable -- otherwise I can't imagine there wouldn't already be an outlet in the living room); you might find there's an opportune place to tap into it a lot closer to your living room than your bedroom is.

Keith wrote:
"But nothing that you can observe on the line has changed."

That`s the problem with electricity. It`s usually invisible. The little old lady asks the trollyman will she be shocked if she steps on a rail. He replies: "Not unless you put your other foot on that overhead wire." The advantage of Cecil`s beloved light energy is its visibility. But, give me a little loop with a panel lamp included, and a neon bulb, and unless this is QRP, I can show volts and amps in the open-wire line before and after the short is placed, and where it occurs.

For low power, I may need more sensitive indicators. For high power, all I need is a florescent tube.

Best regards, Richard Harrison, KB5WZI

>
>Any ideas??

Transmitting the whole content of the cable-TV feed is simply not going to be possible for you to do. You're talking about a massive amount of bandwidth / frequency spectrum - each station is about 6 MHz wide.

You cannot simply hook the cable up to an antenna and "beam" the RF in the next room. Well, you can, but it'd be quite illegal. Many cable channels use frequencies which are _not_ authorized for broadcasting... they overlap the amateur 2-meter band, aircraft and public-safety frequencies, etc. Cable-TV companies have to go to some lengths to keep these signals _inside_ the cable system and keep them from leaking out into free space.

Although it's not what you want to do, the best you're going to be able to manage is probably something like a remote-controllable tuner at the cable-TV jack (think "An old VCR from the thrift store, which has a working tuner and a busted tape mechanism, costing all of $10 as-is") which has a composite-video output, plugged into one of those little 2.4 GHz Part 15 video transmitters. The 2.4 GHz video receiver's composite video (and audio) outputs would be plugged into your VCR's A/V inputs.

You're likely to find the picture quality, and reliability of this arrangement to be less good than you'd like. I used to use something like it to remote-view a TiVo system, and soon decided to switch over to a wired-in arrangement.

Do I read correctly that all the most or all of this stuff is connected case to case, but you are not sure if the whole lot is connected to the electrical installation earth or any other earth systems, ie that it may be floating.

Wouldn't that be something that was quite easy to identify accurately and quickly.

You apparently don't think it important, but it has so much bearing on the likely causes of the problem.

You are right to not assume that the DC power supply -ve terminal is bonded to the electrical earth, practice varies, so test it.

Work out how your station connects to the electrical earth, any substantial metal (eg plumbing, hot water circulation, stormwater plumbing, cladding), and any other earth systems.

When you touch something in your shack and the indicated SWR changes, it is most likely that you have just become part of the RF load on the system, and that means that the thing that you touched is most probably not at ground potential RF wise.

Roy, if you MUST set yourself up as an object lesson, it is better to do so as a warning rather than as an example.

Cec, for the benefit of users of this newsgroup would you mind, please, checking your IEEE dictionary for the meaning of "Insertion Loss/Gain".

To add to the quite unnecessary confusion, people insist on inventing fresh names for this fairly obvious phrase which has been in use by communications engineers for the last 70 years at least.

Thanks for the tips - I installed braids linking all equipment to the
ground lug on the antenna switch, then one braid from there to the
baseboard heater pipe. I polished the copper pipe with a wire
wheel in my dremel tool and attached the braid to it with a stainless
steel hose clamp. This is my 1st residence with baseboard heaters
- makes for a convienant ground!

Now I can touch any component of the station and the needles on
my swr bridge don't move. I moved the bridge among the components
and re-tested - no movement. I also no longer have an RF buzz in

my computer's amplified speakers. Nice. One thing strange, though - I had to trim my power supply's output (it's adjustable from the front panel). It moved from 13.8 to 14.0 volts when I grounded the FT817. Go figure.

My antenna is a 36 foot inverted V (90 deg) with the apex @ 25' and the ends @ 6' and is fed with coax. Before grounding the antenna resonated at 11 & 21 mhz. Now, it's perfectly flat @ 10.220 mhz and not really resonant @ 20 mhz (2:1 swr @ 20.660 mhz) My Z11 can tune it automatically down to 4.000 mhz and manually down to 1.800 mhz. Yes, I know it's not efficiant. Due to firmware limitations I could not test lower than 1.800 mhz but I think I could have gone further - at 1.800 I had an swr of 1.8:1.

72's and thanks for the help, all!

Ken KG0WX

So, when are you going to start using your own head and not depending on others? When will you go through the simple set of equations to find that Vr/Vf = (Zload-Zo)/(Zload+Zo), and there IS NO conjugate on the Zo in the numerator? I went through all that long ago (several years) when someone questioned it, and I trust my calcs. It happens that they agree with those of many, many others.

Which of the following do you not believe? Because if you believe it all, then it's a couple VERY SIMPLE algebraic steps to get to the equation for Vr/Vf.
1. On a TEM line, Vf/If = -Vr/Ir = Zo, which may be reactive.
2. On a TEM line, V=Vf+Vr and I=If+Ir.
3. Where a TEM line connects to a load, the equations in (1) and (2) hold, and V=Zload*I -- because the net line voltage is the same as the voltage across the load, and the net line current is the same as the load current.

Please do us a favor and go do the algebra, and if you get what Besser teaches, show us the steps, and we'll resolve the difference from what we get. If you get what we get, then go take it up with Besser.

Cheers,
Tom

Good, that's the current (no pun intended) RF problem apparently resolved.

For electrical safety, the exposed metal in your station should be equipotential bonded to the electrical system earth. That is better done directly, or through the power outlet, rather than indirectly (eg through the heating system, if that is happening).

I urge you to check that you have an effective equipotential bond from the shack equipment to the electrical installation earth.

Owen

Seems to be the best deal for the money. Had mine for a couple of years and
like it for what it is. I have not sold off my other rigs but have a Yeasu
757 for the low bands and other rigs for VHF/uhf to compair it with.

Yep, it gives me a hint that my accuracy is pretty good where yours sucks.

Energy cannot reverse its momentum without reversing its momentum. If
no other bright rings exist, then it must reverse its momentum.

Checking YOUR work?? I haven't seen anything you've done. You won't
even do the very simple algebra that will show you the right answer,
or at least if you have, you haven't shared it with us.

Why should we not simply ignore you, when you won't do us the courtesy
of going through some simple calcs that we ask you to, so you can see
it for YOURSELF?

Quit hiding behind the skirts of someone else's (flawed) work, and do
a little bit of work yourself, and share THAT with us. If you're
incapable of doing two or three steps of simple algebraic
manipulations to collect linear terms, let us know and we can perhaps
direct you to some help on that.

Bah,
Tom

Well Reg, do you want the definition for 1. audible noise measurements,
2. data transmission, 3. fiber optics, 4. overhead power lines, 5. broadband
local area networks, 6. channel signal loss, 7. general insertion loss, matched
generator insertion loss, matched load insertion loss. ????

Good advice - I guess I should check the outlet for proper
installation then run a braid from the electrical ground to the
copper pipe? My dad owns one of those nifty radio shack
plug in outlet testers - I think I'll borrow it. :-)

Jeez - lots of good advice on this group! Thanks again....

I've had both the original 706 and have had the MKIIG since 2001 and the MKIIG is a great radio. I use it as my base radio. I love the radio, but the only thing it doesn't have going is the ability to be programmed by PC. At least I have yet to find a decent program for it.
There is much better software available for the Yaesu radio's. It makes it a lot easier to program all the channels, if you're using for other than HF. I use it for all the bands, so PC programming would be nice.
But like it just the same.
That's my 2 cents worth.

Lou

Makes for a good enough approximation for most simulations, though.

But if you wanna be anal about it, then:

Strictly speaking: Reflection Coefficient = (Zload-Zo*)/(Zload-Zo)

Where * indicates conjugate.

> Thanks for the poke. 73 Mac N8TT
==========

Mac, you didn't make an arithmetical error. I think you used the wrong value of terminating reactance Xt. Just a Sherlock Holmes deduction. ;o)

The value of terminating reactance which gives greatest possible magitutude of reflection coefficient is equal to the magnitude of Zo which is equal to |Zo| = Sqrt(Sqr(Ro) + Sqr(Xo)).

As you have already deduced, maximum value occurs when the angle of Zo is equal to -45 degrees at which Ro = -Xo.

You incorrectly set the terminating inductive reactance XL equal to -Xo whereas XL should have been Sqrt(2) times greater.

Now if XL is incorrectly made -Xo then the reflection coefficient calculates to Sqrt(5). Which is where your 5 comes from.

Somewhere in these threads I made the exactly same error myself in a non-calculating context where it was not likely to be noticed. The pair of errors, yours and mine, were probably just coincidental.

I do hope I have not just introduced another. ;o)

You appear to be in an educational establishment. There are two programs available from the website below which you may find useful. Download in a few seconds and run immediately programs COAXPAIR and RJELINE3. They have been written according to classical transmission line formulae, generally accurate to all figures displayed and may be used to check other work which uses only engineering approximations. There are others also of educational value.

Things have been getting very ludicrous, to be very kind!

Agreed that no passive tuner will have gain, just as no reflected
power will ever be greater than the incident power fed into a passive
network.

You can't get energy from nothing, folks!

Cec, that is exactly the sort of reply I expected. ;o)

In the present context it can be stated -

INSERTION LOSS due to an electrical network is the additional loss
dissipated in a load when the network is inserted between a generator and
its load. It may actually be a gain. It can be calculated only when both
generator and load impedances are known.

Is it possible to build an antenna that is two inverted vee types with the same central support. I would like to use the idea here: http://www.hamuniverse.com/dipivcal.html but to use four radials, two grounded and two radiators. If no one comments, I'll still experiment with it. but is some one says that this is a bad idea, I'll heed the warning.

Heh, heh...

No it's not!

Unless perhaps the only use you ever make of transmission line dynamics
Engineering
is for simple narrow band ham radio problems!

Try solving some real [i.e. broadband] problems where Zo is not real, not
even close, and
you'll see how important it is to use the whole danged complex expression.

rho = (Z - R)/(Z + R) is a complex function as are both the driving point
impedances the
load termination Z and the reference impedance of the transmission line R.

rho is complex! Get over it.

AFAIK, it is - two inverted VEEs for two different bands.

> but to use four radials, two grounded and two radiators.
Radials with inverted VEE ?? The "inverted VEE" is a sort of dipole, a
symmetrical antenna, uses no radials. Both its wires are "live", even
if it is fed via a coax. (There should be a balun or a choke on the
antenna end of the coax to force symmetrical operation and stop
currents on the outer side of its shielding.) Do not ground any part
of your inverted VEE.

Dovnload INV_VEE.EXE from the superb Reg's software collection
http://www.btinternet.com/~g4fgq.regp/page3.html#S301" and play a bit
about it.

This is what I think, but how can I explain to our managers, who got
the lab set up by a contractor, that they (the 'experts') assembled
the antenna wrongly? what are the possible effects on the measurements
to be made?

As you may have seen in the pdf, the antenna consists of four beams,
in two pairs, meeting at the front (feed point?)

All the longest dipoles are on the right-hand side!

Nope. It needs another radius term...one for the circumference,
and one for the moment arm.

It is my opinion that the confusion over whether to use Zo or Zo*
(conjugate of Zo) in the computation for reflection coefficient arises
because there are two different meanings for the reflection
coefficient itself: one applies to voltage or current waves and the
other applies to "power waves." I do not have the Besser text
mentioned above but a 1965 IEEE paper by Kurokawa also uses the Zo*
term to calculate the reflection coefficient. However, Kurokawa makes
it clear that he is referring to "power waves" and not voltage or
current waves.

The Kurokawa paper was given as the justification for what I believe
is an erroneous equation in the 19th edition of the ARRL Antenna Book.
In all previous editions (at least the ones that I have) the formula
for reflection coefficient uses the normal Zo term. In the 19th
edition the formula was changed to use the Zo* (Zo conjugate) term.

I did some research on this and exchanged emails with some smart
folks, including Tom Bruhns and Bill Sabin. Then I wrote a note to
Dean Straw, editor of the Antenna Book, explaining why I thought the
new formula in the 19th edition was wrong. Here's a copy of that
note:

==========
Email to Dean Straw, 10/5/01

Dear Dean,

A week or so ago I wrote you concerning the formula for rho in the
19th Antenna Book:

rho = (Za-Zo*)/(Za+Zo) [Eq 6, page 24-7]

where Za is the impedance of the load, Zo is the line characteristic
impedance, and Zo* is the complex conjugate of Zo. You replied that
the justification for using Zo* in the numerator is explained in the
1965 IEEE paper by Kurokawa, and that it didn't really make much
difference whether the "classic" formula (Zo in numerator) or the
"conjugate" formula (Zo* in numerator) was used at SWR levels under
100 or so.

I obtained and studied the Kurokawa paper, did some research on the
Internet, exchanged some emails with some folks who know more about
this stuff than I do, and read through all the other technical
literature I have concerning rho. I'm afraid I disagree with both of
your statements (1. Justified by Kurokawa; 2. Doesn't matter for
normal SWR levels). Here's why:

An -infinitely- long line will have zero reflections (|rho|=0). If a line of -finite- length is terminated with a load ZL which is exactly equal to the Zo of the line, the situation will not change, there should still be zero reflections. So if the formula for rho is
rho = (ZL-Zo)/(ZL+Zo)
then |rho| = 0, since the numerator evaluates to 0+j0.
However, if the formula is
rho = (ZL-Zo*)/(ZL+Zo)
then |rho| evaluates to something other than 0, since the numerator evaluates to 0-j2Xo.

To use an example with real numbers: RG-174, Ro=50, VF=.66, Freq=3.75 MHz, matched line loss = 1.511 dB/100 ft (at 3.75 MHz), which yields a calculated Zo (at this Freq) of Zo=50-j2.396. If ZL = Zo = 50-j2.396, then:
|rho(Zo)| = 0 [classic formula, Zo in the numerator]
and
|rho(Zo*)| = 0.0479 ["conjugate" formula, Zo* in the numerator]

Using SWR=(1+|rho|) / (1-|rho|), these two rho magnitude values evaluate to SWR 1:1 and SWR 1.10:1, respectively. So if a line is terminated with a load equal to Zo, which is equivalent to an infinite line, the "conjugate" formula results in a rho magnitude greater than 0 and an SWR greater than 1. This doesn't seem to make intuitive sense.

This same anomaly may be extended to loads of other than Zo and to points other than just the load end of the line. Using the Zo for RG-174 as stated above (Zo=50-j2.396), and an arbitrary but totally realistic load of ZL=100+j0 ohms (nominal 2:1 SWR), I used the full hyperbolic transmission line equation to calculate what the Zin would be at points along the line working back from the load from 0ï¿½ to 360ï¿½ (one complete wavelength) in 15ï¿½ steps. I then calculated the magnitude of both rho(Zo) [classic formula] and rho(Zo*) [conjugate formula] using the Zin values, and plotted the results. Here's the plot:
http://www.qsl.net/ac6la/adhoc/Rho_Classic_Conjugate.gif

(The scale for rho is on the right. The left scale is normally used for R, X, and |Z|, but those plot lines have been intentionally hidden in this case just to reduce the chart clutter.) Note that the plot line for rho(Zo) [classic formula] progresses downward in a smooth fashion as the line length increases, as expected. The rho(Zo*) [conjugate formula] swings around, and even goes above the value at the load point until a line length of about 75ï¿½ is reached. Again, this doesn't seem to make intuitive sense, and I can think of no physical explanation which would result in the voltage reflection coefficient magnitude "swinging around" as the line length is increased.

Of course, the same data may be used to calculate and then plot SWR. Here's the plot:
http://www.qsl.net/ac6la/adhoc/SWR_Classic_Conjugate.gif

Again, this doesn't seem intuitive, and this is for a load SWR much less than 100.

Now if the intent of the "conjugate" formula was to always force rho to be <= 1 and therefore to avoid the "negative SWR" problem, it appears that this has the effect of "throwing the baby out with the bathwater." That is, it may make it possible to calculate a rho value less than 1 and hence a non-negative SWR value in an "extreme load" situation like ZL=1+j1000 ohms (even though SWR is pretty meaningless in that case). However, it also changes the rho and SWR values for completely reasonable loads, such as the example above. At a line length of 45ï¿½, the impedance at the input end of the line is 41.40-j31.29. Using the "classic" rho formula results in calculated rho and SWR values of
rho=0.3095 SWR=1.90
while the "conjugate" formula gives
rho=0.3569 SWR=2.11
Note that these results are for a perfectly reasonable load on a perfectly reasonable line at a perfectly reasonable frequency, but the results differ by an unreasonable amount.

Another point. In the William Sabin article, "Computer Modeling of Coax Cable Circuits" (QEX, August 1996, pp 3-10), Sabin includes the Kurokawa paper as a reference. Even with that reference, Sabin gives the "classic" formula for rho (called gamma in his paper) as Eq 31. When I asked him recently about this, he stated that the article is correct and he stands by the given formula for rho.

Given these various intuitive arguments as to why computing rho with the Zo conjugate formula doesn't make sense, where did it come from? Well, so far I have two candidates:

1) A QST Technical Correspondence article by Charlie Michaels (Nov 1997, pg 70). Michaels gave a formula for computing the portion of the loss on a line that is due to standing waves. That loss formula involves calculating rho by using the "conjugate" formula. The SWR dB loss result, when added to the normal matched line loss number, gives exactly the same figure for total power loss as do other formulas that use completely different techniques (such as in papers by Sabin and Witt). However, the Michaels QST article never said that the rho "conjugate" formula should be used to calculate rho in the general case, only that it should be used as part of an intermediate step to calculate a dB number.

2) The 1965 IEEE paper by Kurokawa, "Power Waves and the Scattering Matrix." Kurokawa does indeed show a formula for -a- reflection coefficient that uses Z conjugate in the numerator. However, in Section I of his paper he explains that he is talking about "power waves" and takes pains to explain that these waves are not the same as the more familiar voltage and current traveling waves. He then goes on to give a mathematical description of these power waves. In Section III he defines the power wave reflection coefficient as

s = (ZL - Zi*) / (ZL + Zi)

where ZL is the load impedance and Zi is the internal impedance of the source. In a footnote he makes it clear that "s" is equal to the voltage reflection coefficient only when Zi is real (no jX component). Finally, in Section IX ("Comparison with Traveling Waves") he explains that when the line Zo is complex the calculations that apply to voltage and current waves are not the same calculations used to determine the power delivered. He ends this section with this statement: "Further, since the traveling wave reflection coefficient is given by (ZL-Zo)/(ZL+Zo) [note no conjugate] and the maximum power transfer takes place when ZL=Zo*, where ZL is the load impedance, it is only when there is a certain reflection in terms of traveling waves that the maximum power is transferred from the line to the load."

To put some actual numbers with this statement, consider the RG-174 from above (Zo=50-j2.396), with a load of ZL=Zo*=50+j2.396. Then

|(ZL-Zo)/(ZL+Zo)| = 0.0479
= small voltage traveling wave reflection
coefficient

while

|(ZL-Zo*)/(ZL+Zo)| = 0
= zero power wave reflection, meaning maximum
power transfer.

Now it seems to me that this clears up the confusion. It looks like it is necessary to consider -two different meanings- for rho. One is for the voltage (or current) traveling wave reflection coefficient. The classic formula to compute that still holds (as Kurokawa states), and that is the rho that should be used when talking about voltage (or current) standing waves on a line. Specifically, that is the rho that should be used in the formula for SWR,
SWR = 1 + |rho| / 1 - |rho|
possibly with an explanation that this formula is only applicable when |rho| < 1.

The -other- meaning for rho is used when dealing with "power waves" or with power and loss calculations as in the Michaels QST formula, and -that- rho (call it rho prime, or maybe some other letter ala Kurokawa) may be defined as
rho' = (Z-Zo*)/(Z+Zo)
However, rho' does -not- have to do with voltage (or current) traveling waves, and may -not- be used to compute SWR. If it is understood that there are two different "reflection coefficients" then everything starts to fall in place, including the last part of the Kurokawa quote above saying that there is a situation when the "voltage" reflection coefficient is slightly greater than 0 while the "power wave" reflection coefficient is exactly 0. Note that no matter what combination of values for Zo and ZL are used, |rho'| will never be greater than 1 (although it can be equal to 1 for purely reactive

loads), thus satisfying the intuitive understanding that there can never be more power reflected -from- a (passive) load than is delivered -to- a (passive) load. But at the opposite extreme, as shown above, "no reflected power" but does -not- necessarily mean "no standing waves."

A further example of the importance of making a distinction between the voltage reflection coefficient and the power reflection coefficient would be the following: Assume a load of ZL=1+j1000 with the RG-174 Zo from above, Zo=50-j2.396. Then

|rho| = 1.0047 (voltage wave reflection coefficient)

and

|rho'| = 0.9999 (power wave reflection coefficient)

This shows that the reflected voltage is slightly greater than the incident voltage, at least at the point of reflection, before the line loss has caused the calculated (or measured) rho to decay. It further shows that the reflected power is still less than the incident power, thus not violating the principal of conservation of energy. Robert Chipman, "Theory and Problems of Transmission Lines," presents a mathematical proof of this, including this quote from page 138: "... a transmission line can be terminated with a [voltage] reflection coefficient whose magnitude is as great as 2.41 without there being any implication that the power level of the reflected wave is greater than that of the incident wave."

In summary, I think a distinction must be made between the "voltage" reflection coefficient and the "power" reflection coefficient, and therefore I think the following changes should be made to the 19th edition of the Antenna Book:

1. Revise the initial equation for rho [Eq 6, page 24-7] back to the classic "non-Zo*" form, since rho is used in this context as the voltage reflection coefficient.

2. Equation 11 on page 24-9 is
rho = sqrt(Pr/Pf)
where Pr and Pf are the reflected and forward power levels. Intuitively this seems to be the "second" definition for rho, namely the power reflection coefficient, although my math skills are not up to the task of proving that this formula is the equivalent of the Kurokawa formula for the power reflection coefficient 's'. Perhaps this formula should have a footnote indicating that it refers to the "power" and not "voltage" reflection coefficient, and that the two are technically equal only when the Xo component of the line Zo is ignored. (The same point as is made in the Kurokawa footnote referred to above.) Given the precision to which most amateurs can measure power, and the fact that under normal circumstances the line loss and hence the Xo value is much smaller than that of RG-174, of course this point is moot in a practical sense.

3. If Equation 11 is for the "power" reflection coefficient, then Equation 12 is a mixing of apples and oranges. Perhaps the second equal sign could be replaced with an "almost equal" sign.

4. Equation G in Table 2 "Coaxial Cable Equations" on page 24-20 should remain as is, since it obviously is referring to the voltage reflection coefficient.

Thanks for looking this over, Dean. I would certainly welcome any comments or feedback you might have.

73,
Dan Maguire AC6LA
==========

I don't know if Dean has changed the formula in later printings of the 19th edition or in the upcoming 20th edition. He responded that he was busy with other matters and would get back to me later. He never did and I let the matter drop.

I have the Kurokawa paper in pdf format. If anyone would like a copy, drop me a private email and I'll be glad to send it to you. The two charts mentioned above were produced with a modified version of the XLZIZL Excel application. XLZIZL is available free from www.qsl.net/ac6la.

Get over what? Rho is the magnitude of the Reflection
Coefficient, which can certainly be complex, but Zo is often assumed
to be real.

OK! OK! If you wanna be anal about it, then:

Strictly speaking: Reflection Coefficient = (Zload-Zo*)/(Zload-Zo)

Where * indicates conjugate.

Look it up...

My 706 has worked great for 2 or 3 years, however, my mkiiG has some problems.
1) my ssb power is only 30 watts on 20-160 meters. (AM power and rtty Power is ok)
2) SWR and Power Meters seem to be reversed on 20-160 meters.
I use an external tuner to verify this.
3) 440 does not seem to receive.
4) Local service people (Avvid) does not work on the G model
5) Guess it will have to go back to Icom for alignment at $75 / hour

I have Diamond CP6 on top of 10 stoy building. That's about 55m off the ground. It works great on 10m! Big problems on 15m (it takes me a lot of time to get through to DX stations), I don't have license for 20m, and nice performance on 80m. It is 4.6m long and have one radial for each band (6 radials, 50MHz, 28/29MHz, 21MHz, 14MHz, 7MHz, 3.5MHz).

It is nice antenna for porable use, simple to assemble and short for transport. But for real work I think I will get me GAP Titan.

Hope you will get something that will work for you. :)

Please think carefully about your reply.

Energy = Force x Distance

When I push the block in a square pattern, the distance is the sum of
the sides of the square.

When I push the block in a circle, the distance is the circumference,
which is 2 x pi x Radius.

If, after reviewing the above, you still think the radius needs
squaring, please explain why the equation for energy when pushing
in a circle is different than that for pushing in a square.

As an exercise, consider pushing in a triangle pattern, a square
pattern, pentagon, hexagon, heptagon, octagon, ...

Each pattern above is getting closer and closer to being a circle;
at which pattern does the equation for Energy change from being
the distance moved to being twice the enclosed area?

And I forgot to say...

In a rotary system, it is often deemed convenient to think of Distance
in terms of rotations or angular displacement.

Torque is just a way of thinking about Force so that you can use
angular displacement instead of distance.

I am using the 706MKII (not G model) mobile and have had great results with it.

I have used it with a Webster Bandspanner antenna and also a hamstick antenna. I am currently using it with the AH-4 antenna tuner and the 20m hamstick and results are good. The advantange, of course, to the tuner, is I can instantly change bands on the antenna system at the push of a button.

I have also used my 706 in a portable operation. Last year, I went to the island of Bonaire on vacation. I packed my 706 in a foam padded briefcase along with a small tuner, a switching power supply, and carried a homemade 20 meter dipole. Had a great time, LOTS of contacts all over the US and Europe.

Dr. Slick wrote:
"And if the permittivity (impedance) of the material surrounding an antenna will affect its input impedance, I think it is something to consider."

The permittivity surrounding our antennas rarely changes and is the same for nearly all antennas.

My dictionary says of permittivity: "See Dielectric Constant".

Velocity can be affected by dielectric constant as is seen in solid-dielectric coax. Fortunately, the dielectric constant of the environment our antennas operate in is nearly constant.

Were matching antennas to 377 ohms significant, it would manifest itself in the century of experience of using many antennas of many differing types.

Best regards, Richard Harrison, KB5WZI

3766. re: Rockwell Collins "PropMan 2000" propagation s/w

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-21 13:29:06 UTC
From: "Carl R. Stevenson" <wk3cqth@wk3c.com>
Message-ID: <CO31b.1200$6e5.91003@nnrp1.ptd.net>
Source record: 110110
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.dx

For those of you who have the Rockwell Collins
"PropMan 2000" propagation prediction s/w
package, you may have noticed that the program
no longer retrieves "Space Weather" input from
the internet automatically, but gives error messages.

This is due to the fact that the sources of the data
have changed because of several factors:

1) NOAA has switched satellites for some of the proton
data, due to operational considerations ... this caused
filenames to change (old filenames based on satellite x
are no longer being updated, but the equivalent data is
now available from satellite y)
2) directory structures on the servers have changed

I have created a new "propman.ini" file that contains
the information necessary to retrieve the space wx
data. It is available for amateur use on my personal
web page at http://home.ptd.net/~wk3c

The SSN (smoothed sunspot data) is no longer available
automatically, but can be retrieved and entered manually
from http://www.nwra-az.com/spawx/env_latest.html

use the "NWRA SSNe" data from the rightmost column
for the current date.

I hope this information is helpful. I have been talking with
the engineer at Rockwell Collins and he has verified that
my propman.ini works correctly. They are also considering
modifying the parser that read the old SSN data file to extract
the SSN data from the website above (if they implement this,
it will require another change to propman.ini to point to the
website so the program can "see" and parse the SSN data)

73,
Carl - wk3c

Source record: 110111

We made the transition in June. Very straightforward.

If you are using Internet Explorer/Outlook from Microsoft then simply
click on the Comcast address given, download the program, and restart
your computer on the date specified. It will automatically transfer all
relevant info for the transition.

If you are not using Internet Explorer then you will have to manually
transfer the information for your POP3, email, and newsgroup by hand. I
use Netscape 7.1 and it took about 2 minutes to make the changes.

Comcast will automatically forward email from the ATTBI.com address to
your COMCAST.net address for about 1 to 1 1/2 years.

Comcast switched us, wife and I on LAN, on 1 July without a hiccup. My
wife uses IE/Outlook and I use Netscape.

Thanks for the reply, Richard. I will look around for mounting options. I would like to keep it mounted as high as possible because I am often in places where I ford deep water and mud. The higher the better to keep the elements out of the workings.

> point should be out of reach).

Myself, I would tune them, or have them very close. Or at least on the preferred band. Better decoupling from the feedline for one thing. If the radials do not present a low Z for a certain band, they won't work too well at all. I would grount mount if I didn't want to tune the radials. It's going to be very hard to get proper performance on all bands with only one tuning setup, unless maybe he uses an autotuner of some type. "elevated"
I'd pick the most likely used bands and build for those. IE: it will be hard to run 40 and 20 both, with good results on both bands. If I ran 40/17m as the main design, I'd forget about 20m. And visa versa. If not, be prepared for mediocre results on one of the bands. I've never tried feeding an elevated GP/non resonant radials with ladder line and a tuner. I know it can be done, but I wonder about the amount of common mode currents and performance on "non radialed" bands, compared to a normal setup with 1/4 wave radials.
>
> Be aware that as impressive as it may feel, the height may be a
> detriment in the higher HF (too long and radiation will be skyward,
> bound).

Not the height, but the length of the antenna is too tall for the higher HF bands for good low angle performance. IE: 10-12 meters. It will be ok 15m down.
This is probably what you meant...

Lightspeed? Oh yes, you can show kids that they have 11 fingers!

First grade kid is best.

me:
lets count your fingers. You don't mind if we count up or down?
does it matter?

kid:
no

me:
grabbing one hand of the kid
'OK, let's start. (countings slowly) 10, 9, 8, 7, 6'
'you said, doesn't matter counting up or down?'

kid:
no, does n't matter

me:
ok, let's continue, where did we stop, yeah 6,
(grabbing other hand) hmmm, let's count up now!
(counting fast) 7,8,9,10, 11 - oops, you got 11 fingers?

...faster than speed of light!

Not braid for this application. Use solid copper #6 or larger. The
National Electrical Code specifies that all the grounds must be tied
together and how it should be done. There are many good reasons for this,
not the least of which deals with the effects of lightning. If you live in
an area where thunderstorms occur, you really need to look into the
grounding issue. Multiple isolated grounds can be far worse than none at
all! By the way, does that copper baseboard heating pipe really have a
continuous conducting path to earth ground?

3772. RF still in the shack?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-21 13:56:02 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <aMudneQWMajuUtmiXTWJkg@comcast.com>
Source record: 110117

Here I am again, probing your minds for advice:

I have 3 swr meters in my station - 1) my FT817, 2)
my MFJ 860 and 3) my Z11 autotuner

All equipment is grounded together then to a baseboard
copper heater pipe with 1/4" tinned copper braid. When
I transmit, I can touch any piece of equipment and none
of the meters show any change.

Antenna is a 36' unverted V without balun (for now), fed
with 12' of rg8x coax. Apex @27', ends @ 6'. Antenna
resonates perfectly @ 10.220 mhz. (It shoud'nt - it's way
too short for that freq)

Here's the issue:

Sometimes my Z11, the last component before the ant.
will indicate a <1.5:1 match after tuning while both the MFJ
tuner and the FT817 indicate a 2:1 swr. A minor tweak
of the Z11 produces a flat match indication on all equipment.
Sometimes the Z11 will show a 2:1 swr while the other
two meters will agree with a flat match. In any case, the
MFJ swr bridge and the FT-817 *always* agree with each
other.

I'm guessing that because I don't have a balun (I'm planning
on buying a 1:1 Van Gordon balun next month), RF is traveling
down the feedline to the Z11 and throwing the match
indication off.

Is this correct? The problem only happens on certain bands:
(I started testing @ 5 mhz & stopped @ 30mhz)

8.000 mhz 20.000 mhz
15.000 mhz 21.000 mhz
17.000 mhz 23.000 mhz
18.000 mhz 26.000 mhz
19.000 mhz 27.000 mhz

Thanks for any advice ya'll can give me.

72's de Ken KG0WX

Hummm. I thought Cliff worked on those....Guess not. My friend took
his over to Houston amateur supply or whatever they call it. Spring
TX. "George is the tech" He seemed to be able to fix it..

> 5) Guess it will have to go back to Icom for alignment at $75 / hour

That would be my first choice. Probably costs more, but I like the
idea of the factory working on it. "Mods updates, overall tech
quality, etc.."
I've got a 706mk2g, but no real problems so far after 2.5 years or so,
and that radio is on 24/7 nearly. It's my main casual listening radio.
I've got it on AM-740 right now as I type. :/ MK

Hi Abdullah,

Ask them for a refund, and drop them from your vendors list.

What effect did it have? Sorry to say this, but it sounds like you are going to spend far more money doing it yourself than if you had simply farmed out the job to a real lab that was registered with the FCC.

It looks like you are correct. Sorry for the mistake, it's been
too
long since i've done a torque problem! I'm more of a EE!

Look at this page:

http://www.sinclair.net/~ddavis/170_ps10.html

If you agree that torque is in units of N*m, then according to this
page, you have to multiply this by the angular displacement, which
will be 2*pi for a full revolution. I was incorrectly trying to
multiple by the actual circumference traveled, which is incorrect
because we want angular displacement instead.

To me, this kinda shows how torque is closer to work than just
force, because with torque, you just need to and the angular
displacement (dimensionless) to get the work done.

Thanks for the review, Keith.

I agree with you that almost all antennas are surrounded by air or
something very close to free-space (outer-space).

Many have agreed with me that a water-proof antenna emmersed in
water will change in it's input impedance, because of a different
dielectric constant.

I'm not sure how many antennas are designed for underwater use,
but it doesn't matter for the sake of arguing that the antenna
"matches" to the impedance of the material that surrounds it.

May I remind you, Richard, that it was you who brought up the subject of bench testing (as if testing cannot be done without a bench). I merely responded to your requirement for a bench. My bench was a card table in my back yard. That's exactly where I did my variable length transmission line testing - in my back yard in Queen Creek, AZ on a pleasant spring or fall day (I forget which). It wasn't boiling and it wasn't freezing so it must have been spring or fall. :-)

Oh, and allow me to add: Like my EE prof at Texas A&M in the 50's, I consider instantaneous power to be a completely useless concept, fully appropriately related to how many angels can dance on the head of a pin. After all, how much power can traverse a point in zero time?
Hint: energy per delta-t if t=0 is zero!

I will never forget my prof's words: "Instantaneous power is about as useful as tits on a boar hog." But I have an open mind - please convince me that you are more brilliant than the head of the EE department at Texas A&M.

3793. how rf leave the antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-21 17:23:47 UTC
From: george_micheal987@yahoo.com
Message-ID: <91472d9c.0308210923.5a450b85@posting.google.com>
Source record: 110036

If an rf source is applied at the A end of the length of wire from A to B, the wave will travel along the wire until it reaches the B end. Since the B end is free, an open circuit exists and the wave cannot travel . This is a point of high impedance. Then the wave back (reflects) from this point of high impedance and travels toward the starting point, where it is again reflected. The energy of the wave would be gradually dissipated by the resistance of the wire of this back-and-forth motion (oscillation);

rf source A .____wire____.B

So how rf leave the antenna ???!!!!!!

in practical we use this configration :

---------- Antenna
rf source (transmmiter) ----|
---------- dummy load

Thanks

Hi Cecil,

Yes, it was me, and you drew on the less than full context of that
message to wander into these aimless amblings.

Notice you've done it again by focusing on the bench and clipping off
the mention of being data-phobic. You continue to evidence that
choice in avoiding the technical with your response here.

This is certainly not your fault, when it shows such a high rate among
the correspondents here.

Perhaps this forum should be re-named rec.radio.ouija.antenna.

My 1993 70th ed. of the ARRL handbook assumes the Zo to be always
purely real.

I believe the Zo* version is correct. The purely real Zo version
is correct too, but Zo must be purely real.

I think i does make sense in the sense that if the source
(reference) and the load both have reactance, that there WILL be some
reflections.

If ZL=Zo*=50+j2.396, then the capacitive reactance is indeed
canceled, and you are matching a pure 50 ohms to a pure 50 ohms again,
and the numerator will be zero, as it should be.

This is what impedance matching is all about really, not just
getting the real part of the imedance the same, but cancelling any
reactance.

The conjugate formula is correct.

>

I'm not totally sure if you did this right, but if the
transforming transmission line had reactance in it, and you are
measuring everthing from
Zo=50-j2.396, then i would expect the rho to swing up and down the
same way every 1/2 wavelength, as your data shows.

>
> A further example of the importance of making a distinction between

If you had used the conjugate Zo* formula, you get

[rho] = 0.99989 which matches the bottom result.

I stand by the Conjugate formula, even more now.

A big deal is being made of the general assumption that Z0 is real.

As anyone who has studied transmission lines in any depth knows, Z0 is, in general, complex. It's given simply as

Z0 = Sqrt((R + jwL)/(G + jwC))

where R, L, G, and C are series resistance, inductance, shunt conductance, and capacitance per unit length respectively, and w is the radian frequency, omega = 2*pi*f. This formula can be found in virtually any text on transmission lines, and a glance at the formula shows that Z0 is, in general, complex.

It turns out that R is a function of frequency because of changing skin depth, but it increases only as the square root of frequency. jwL, the inductive reactance per unit length, however, increases in direct proportion to frequency. So as frequency gets higher, jwL gets larger more rapidly. For typical transmission lines at HF and above, jwL >> R, so R + jwL ~ jwL. G represents the loss in the dielectric, and again for typical cables, it's a negligibly small amount up to at least the upper UHF range. Furthermore, G, initially very small, tends to increase in direct proportion to frequency for good dielectrics like the ones used for transmission line insulation. So the ratio of jwC to G stays fairly constant, is remains very large, at just about all frequencies. The approximation that jwC >> G is therefore valid, so G + jwC ~ jwC.

Putting the simplified approximations into the complete formula, we get

Z0 ~ Sqrt(jwL/jwC) = Sqrt(L/C)

This is a familiar formula for transmission line characteristic impedance, and results in a purely real Z0. But it's very important to realize and not forget that it's an approximation. For ordinary applications at HF and above, it's adequately accurate.

Having a purely real Z0 simplifies a lot of the math involving transmission lines. To give just a couple of examples, you'll find that the net power flowing in a transmission line is equal to the "forward power" minus the "reverse power" only if you assume a real Z0. Otherwise, there are Vf*Ir and Vr*If terms that have to be included in the equation. Another is that the same load that gives mininum reflection also absorbs the most power; this is true only if Z0 is assumed purely real. So it's common for authors to derive this approximation early in the book or transmission line section of the book, then use it for further calculations. Many, of course, do not, so in those texts you can find the full consequences of the complex nature of Z0. One very ready reference that gives full equations is _Reference

Data for Radio Engineers_, but many good texts do a full analysis.

Quite a number of the things we "know" about transmission lines are actually true only if the assumption is made that Z0 is purely real; that is, they're only approximately true, and only at HF and above with decent cable. Among them are the three I've already mentioned, the simplified formula for Z0, the relationship between power components, and the optimum load impedance. Yet another is that the magnitude of the reflection coefficient is always <= 1. As people mainly concerned with RF issues, we have the luxury of being able to use the simplifying approximation without usually introducing significant errors. But whenever we deal with formulas or situations that have to apply outside this range, we have to remember that it's just an approximation and apply the full analysis instead.

Tom, Ian, Bill, and most of the others posting on this thread of course know all this very well. We have to know it in order to do our jobs effectively, and all of us have studied and understood the derivation and basis for Z0 calculation. But I hope it'll be of value to some of the readers who might be misled by statements that "authorities" claim that Z0 is purely real.

One more thing. I've never seen that conjugate formula for voltage reflection coefficient and can't imagine how it might have been derived. I've got a pretty good collection of texts, and none of them show such a thing. If anyone has a reference that shows that formula and its derivation from fundamental principles, I'd love to see it, and discover how the author managed to get from the same fundamental principles as everyone else but ended up with a different formula.

I got one a couple of months ago--they've dropped the price
and I couldn't resist. I got it really to work 6 meters but
wound up putting it in the car instead. I am REALLY impressed
with it. The DSP/auto-noise-reduction stuff seems to work
remarkably well (I've never had it before so I'm not a very
serious judge, though.) The menu system is pretty easy to use
even in the car, and the memories are darned nice--they store
power level among other parameters, so I can switch between the
local repeater and low power, and 70 watts on 20 meters, just with
the flip of the knob. VERY nice. I've only owned 4 HF rigs in my
entire 14 years as a ham, so I'm not very experienced with rigs
in general. But I've been DELIGHTED with the 706 MkIIG. If I
ever get bored with HF mobile I'll probably bring it inside for
my main SSB rig and use my FT-840 for PSK and CW. Feel free to
email me if you have any specific questions .. GOOD LUCK!

For the record I wrapped 6 turns of rg-8x in a 2-5/8"
diameter loop - I used a round glue bottle as a form,
applying superglue to the coax then drying it with
baking soda (cures superglue on contact).

I ended up with a real nice looking coil......

I also lengthened my antenna to 26'7" per leg (that
was all the spare wire I had on hand). The antenna
now resonates at 8 mhz exactly.

Question - if I trim the antenna for resonance on 40m,
will I loose efficiancy on 60m? I think yes but I could
be wrong - nobody's perfect.....

Except maybe Cecil...... ;-)

George Micheal wrote:
"So how rf leave the antenna?"

The end-fed wire antenna is a circuit completed by capacitance to ground and its return to the transmitter.

In a good antenna system, only a small percentage of the total r-f is lost in wire, ground, feedline, etc. Nearly all is radiated.

A current-carrying wire is surrounded by magnetic lines of force as exhibited by solenoid magnets, motors, etc.

An electrically charged item radiates an electric force field as exhibited by an Ace comb`s attraction for bits of paper under the right conditions.

A varying magnetic field can induce an electrical potential in a wire. It happens in common electrical generators. Likewise a varying electric field can alternatly attract and repel electrons, thereby producing an slectric current capability.

R-F circulating in the antenna wire produces alternating magnetic (H)-fields and electric (E)-fields around the wire.

The question is what impels these fields to travel to much greater distances than static fields travel. J. C. Maxwell speculated that displacement current of the sort that flows through the dielectric of a capacitor is surrounded by magnetic flux the same as current through a wire is. He was right.

Displacement current requires no electron flow. Note that we have vacuum capacitors where the space between the plates is completely void.

Displacement current makes the radio wave self-perpetuating. An H-field out in space creates an E-field by generating a "potential difference" which produces a "displacement current" which in turn generates a "potential difference" as represented by the E-field, which generates a "displacement current" as represented by the H-field.

This back and forth energy swap between E&H fields just goes on and on.

Best regards, Richard Harrison, KB5WZI

This is what I did: Icom756 > Coax1 > Kenwood SW2000 > Coax2 > Drake Dummy load. Frequency = 14.25

With Coax1 being 50 Ohm coax (LMR240), the SWR was 1:1.

I then changed coax1 to precisely 1/4 wavelength of 75 Ohm RG59. Clearly the loading changed because the transmitter was now seeing 112 Ohms. When I adjusted the 756 for the same calibration voltage on the SW2000, the SWR was still 1:1.

Next I used a T connector and paralleled 2 dummy loads. The Icom did not like that, and reduced power from my initial 30W to about 22W. The Kenwood should have read 2:1, but instead read 1.7:1 *for both the 50 Ohm and 75 Ohm coax1*
Is this what you are talking about?

:> ----
:> Reg, G4FGQ

The calculation of the skin effect current in a pipe is straightforward
but has a few numerical problems as Roy noticed. Please note that I have
not checked my results carefully. To get a handle on the problem it
is simplest to analyze something like a coaxial cable with a perfectly
conducting outer conductor and a hollow inner conductor made of a good
conductor like copper. You can then show that the outer conductor does
not change the current distribution measurably. Further since you know
the fields in coaxial cable pretty well it is easy to identify good
approximations.

Perfect coax is a waveguide operating in the transverse electromagnetic (TEM)
mode. With imperfect conductors, there must be an electric field along
the conductors to drive the current from Ohm's law J = sigma E. Therefore
this can no longer be a transverse electromagnetic mode since E is no
longer transverse. The current however is still just in the direction of
the axis, so the magnetic field will still be transverse and the mode
with imperfect conductors is transverse magnetic. The usual waveguide
simplifications can be made. The fields for a wave propagating in the
z direction have an e^{i k z} dependence (I assume e^{- i w t} time
dependence; substitute i=-j everywhere if you prefer e^{j w t} time
dependence). Everything can be calculated in terms of E_z the z component
of the electric field. In particular in SI units it satisfies a Helmholtz
equation,
1/rho d/drho rho d E_z/drho + gamma^2 E_z = 0,
where gamma^2 = mu epsilon w^2 -k^2 and the magnetic field is
H_phi = i epsilon/gamma^2 dE_z/drho.
E_z and H_phi must be continous at the inner conductor boundaries, while
E_z = 0 on the perfect conductor and is well behaved at the origin.
As Roy says the solutions of the Helmholtz equation are combinations of
two Bessel functions in each region. Matching the boundary conditions
then finds the coefficients and the appropriate value of k, and the
solution is complete.

Now let's make some approximations. Since we know the mode is close
to the TEM mode we know that in the vacuum regions, gamma^2 must be
very nearly zero since it would be exactly zero for the TEM mode. In
the conductor epsilon has an imaginary part proportional to sigma/w,
which gives a term enormously bigger than the k^2 term or the real
part. Therefore, we find that the k^2 terms can be dropped from the
calculation. Once that is done, the outer conductor no longer plays a
part in the solution, and we no longer have to consider it.

Look at solution in the interior of the inner pipe. Normally it would be
proportional to the Bessel function J_0(gamma rho), but we saw that gamma
in vacuum for a near TEM mode is very close to zero. J_0(x) goes like
1-x^2/2 for small x, so the electric field inside is nearly constant,
and the magnetic field is nearly zero. Matching boundary conditions at

the inner surface of the inner conductor therefore requires to a good approximation a nonzero E_z with a zero derivative. The current density is simply J = sigma E_z, so the form of the current inside the pipe is
J(rho) = A J_0[(1-i) rho/delta] + B N_0[(1-i) rho/delta]
where J_0 and N_0 are the Bessel and Neuman functions (N_0 is also written Y_0 sometimes) and delta is the skin depth. The coefficients A and B must be chosen so that the rho derivative is zero on the inside of the pipe, and the integral of J gives the total current desired. The power loss is then the integral of |J|^2/2*sigma.

As Roy noticed, for a reasonable size inner conductor, rho is always an enormous number of skin depths so the arguments of the Bessel functions are large, and the Bessel functions have large exponentially growing parts so that it can be numerically difficult to calculate the coefficients A and B. It is therefore best to use the large argument asymptotic expressions:
J_0(x) = sqrt(2/pi x) cos(x-pi/4)
N_0(x) = sqrt(2/pi x) sin(x-pi/4)
and isolate the divergent part. However, in the usual case, we can ignore the curvature of the pipe to a good approximation. That is, if the pipe is many skin depths thick, the result will be the same as a solid pipe, which is B=0. If on the other hand it is only a few skin depths thick, then rho will change very little across the pipe, and we can replace the rho in the square root with the value at the outer radius. In that case, it is easy to satisfy the boundary conditions and the result is approximately:
J(rho) = I [(1-i)/(2 pi b delta)]
[cosh((rho-a)(1-i)/delta)/sinh((b-a)*(1-i)/delta)]
where b and a are the outer and inner radii of the conductor.
The total current is 2*pi*b int_a^b drho J(rho) = I by construction.
Calculating the effective resistance from the power loss gives:

R_effective = R_infinity *(sinh(2*t)+sin(2*t))/(cosh(2*t)-cos(2*t))

where R_infinity is the resistance for a solid pipe, and t is the pipe thickness in skin depths = (b-a)/delta,
R_infinity = 1/(2*pi*sigma*delta*b). The minimum is at t=pi/2 which is approximately 1.6 skin depths as Reg mentioned. It takes the value R_infinity*tanh(pi/2) or about 0.92*R_infinity. For t>3, the difference between the pipe and the solid wire is less than a half a percent.

I would be pleased to hear from Reg if the plot of the equation above agrees with that in his reference.

===HFpack Events 18 OCT 2003 at Pacificon===
HFpack. The HF Portable Group.
http://www.hfpack.com

HFpack Pedestrian Shootout 2003
HFpack Portable HF Forum
HFpack Snack 'n Drink Session
HFpack Zombie Walk 'n Talk Session

Pacificon 2003 Convention in San Ramon California USA
Friday 17 Oct through Sunday 19 October

HFpackers from all over the world will converge at the annual HFpack events in California. The HFpack Pedestrian Shootout 2003 is different this year, and includes measurements of complete Pedestrian Mobile backpack systems. The new rules will be announced soon. The HFpack Portable HF Forum is a powerpoint presentation and live demo of state-of-the-art portable systems by HFpackers. The HFpack Snack 'n Drink gives everyone a chance to relax and talk together. The HFpack Zombie Walk 'n Talk is a casual evening /PM session with portable gear outside in the beautiful California environment.

See Map and information on HFpack's Website.
http://www.hfpack.com
The HFpack talk-in and intercom frequencies are:
18157.5kHz USB and 144.320 MHz FM Simplex (PL 100)

Saturday 18 October 2003
11:30AM to 2:00PM HFpack Pedestrian Shootout 2003
Location: San Ramon Central Park, Bollinger Canyon Road
Pack a lunch. Bring your best Pedestrian Mobile pack.
Frequencies: 5371.5kHz USB, 14342.5kHz USB.

Saturday 18 October 2003
3:45PM to 4:45PM HFpack Portable HF Forum
Location: San Ramon Marriott, Forum Room "Salon G"
Powerpoint presentation by KQ6XA. Live Demos by HFpackers.

Saturday 18 October 2003
5:30PM HFpack Snack 'n Drink
Location: Pasta Pomodoro restaurant, 146 Sunset Drive,
next to Marriott Hotel
Gather with fellow HFpackers around the patio tables.

Saturday 18 October 2003
8:45PM HFpack Zombie Walk 'n Talk

Location: San Ramon Marriott hotel front lawn.
Frequencies: 5371.5 USB, 7242.5 LSB, 3997.5 LSB

> Z0 is, in general, complex.

A good approximation to Z0 is:

Z0 = R0 sqrt(1-ja/b)

where Ro = sqrt(L/C)
a is matched loss in nepers per meter.
b is propagation constant in radians per meter.

The complex value of Z0 gives improved accuracy in
calculations of input impedance and losses of
coax lines. With Mathcad the complex value is
easily calculated and applied to the various
complex hyperbolic formulas.

3816. Re: Vee vs. Dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-21 22:08:15 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vkagmdf2sk825@corp.supernews.com>
Source record: 110060

Yes and no. Gain is a single number, so it's a poor and inadequate description for the three-dimensional pattern of an antenna.

An inverted vee has considerably higher gain off the end than a dipole, at most elevation angles of interest for long distance communication.

Broadside, the pattern of an inverted vee is very much like the pattern of a dipole at a height equal to the height of the inverted vee 1/3 of the way from the center. Consider, for example, an inverted vee whose center is at 50 feet and ends at 20 feet. 1/3 of the way from the center is at 40 feet, so the pattern will look a lot like a dipole that's 40 feet high.

You can see just what the pattern of each antenna looks like in all directions by downloading and using the free EZNEC demo program from http://eznec.com. After installing, start the program, click Help, read the Getting Started section, and go through the Test Drive tutorial. It takes you through the design and analysis of a dipole and an inverted vee.

Look at the azimuth and elevation angles you'll be using for communication, and you'll easily see which one would be better and by how much.

Fascinating... Please have a look at the following reply I got from
Besser... I still wish people would go through the simple math
themselves, and make up their own minds what's correct and what isn't.
I gather that Slick has made up his own mind, though see no evidence
that it's on the basis of the simple calcs from what I believe he
already agrees with. Oh, well, not MY problem. (This is twice now,
recently, that I've followed up on other people's references and found
them to be at best questionable in some way.)

Cheers,
Tom

=-=-=-=-=-=-=-=-= Beginning of quoted material =-=-=-=-=-=-=-=-=-=-=-

Hello Tom-

Thank you for your message. I do not know which specific course was
referenced by the person you mentioned in your message, but I did
check
the notes for our more popular course which covers linear RF circuits.
In the manuals for that course, the formula is given as you described,
except that the Zo term in the numerator is _not_ the complex
conjugate.
Thus the formula in the manual reads:

Gamma = Vr/Vf = (Zl-Zo)/(Zl+Zo)

This is in agreement with Guillermo Gonzalez's text, "Microwave
Transistor Amplifiers," which is one of the references used in writing

the course.

Please let me know if this information addresses your concern.

Have a good day.

Regards,

Rex

---

name: Tom Bruhns

body: I have recently seen someone attribute to Besser Associates
training a formula for reflection coefficient at a load Zl as Vr/Vf =
(Zl-Zo*)/(Zl+Zo), where Zo* is the complex conjugate of the line
characteristic impedance Zo. I'm curious if this is actually what you
teach, as it is counter to what is commonly in texts, and is also
counter to the commonly accepted boundary conditions on a TEM line at
such a load.

Yours in the interest of accurate models,
Tom Bruhns

3819. Bricks effect in dipole resonance? Help!

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-21 23:14:33 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <kbqdnUpeoaQbz9iiU-KYgw@comcast.com>
Source record: 110063

What effect would a brick wall have on a HF antenna?
I'm talking 1-2" distance from the bricks, folks. The
wire used is 22 ga stranded insulated speaker wire.
Now no lectures about power - I run QRP. :-) The
station is well grounded to a copper baseboard heater
pipe and all components have short runs (12" or less)
of 1/4" braid line going to a common point. From there
it's 1/4" braid (26" long) to the pipe. I can touch any
part of the system while transmitting and see no change
in SWR.

I cut an inverted V 66'7" per leg 133'2" overall. It's fed
with 12' of rg8x coax with a 6 turn 2-5/8" dia coil at the
feedpoint. The apex of the antenna is roughly 25' up. The
ends of the antenna are at chest height. The antenna is bent
around the corner of my building 90 degrees (I'm in a
corner unit). The last 8' of each leg bends again 90 degrees.

The antenna resonates as follows:
============
2.130 2:1 swr
2.715 1:1 swr (flat)
3.620 2:1 swr
============
8.970 2:1 swr
9.210 1.8:1 swr
9.390 2:1 swr
============
12.230 2:1 swr
13.040 1.9:1 swr
13.850 2:1 swr
============
15.930 2:1 swr
============
20.970 2:1 swr
22.745 1.2:1 swr
24.520 2:1 swr
============

If I figure 468/133.1666666667 I get 3.514.393 mhz
for resonance How come the antenna is so far off?
Could it be the height? Not that I'm complaining - I
like the low resonance and my Z11 autotuner will take
this antenna down to 1.8 mhz real easy. Although at
that freq I expect the antenna will radiate a NVIS

signal due to low HAAT.

Any ideas???

> thing.
[snip]

You are absolutely correct Roy, that formula given by "Slick" is just plain
WRONG!

rho = (Z - R)/(Z + R)

Always has been, always will be.

Where does that "Slick" guy get his information? And where does "Slick" get
off with all of his "potifications"??? I dunno... *He* thinks "Besser",
"Pozar" and
ARRL are authoritative sources for transmission line technology!!!

Me?

I have made a living as a professional Engineer designing transmission
equipment over
the past four decades, currently more than $4BB gross shipped to world wide
markets,
where the Zo I used is neither real, nor a constant!

And what is more... I have never consulted any of those three authorities
referenced by
"Slick". I certainly don't think of them as being authoritative, "cream
skimmers"
perhaps, but not certainly not authoritative.

I believe that "Slick" has gotta stop "pontificating" and start reading in
better circles...
much better!

The usage of complex conjugate Z0* becomes
significant when calculating very large values of
VSWR, according to some authors. But for these
very large values of standing waves, the concept
of VSWR is a useless numbers game anyway. For
values of VSWR less that 10:1 the complex Z0 is
plenty good enough for good quality coax.

W.C. Johnson points out on page 150 that the concept:

Pload = Pforward - Preflected

is strictly correct only when Z0 is pure resistance. But the calculations of real power into the coax and real power into the load are valid and the difference between the two is the real power loss in the coax. For these calculations the complex value Z0 for moderately lossy coax is useful and adequate.

The preoccupation with VSWR values is unfortunate and excruciatingly exact answers involve more nitpicking than is sensible.

I was looking at a 2.4 GHz antenna that had 20 1/2 waves in phase.
Then there was the same antenna, almost, except it said it had a 3
degree downtilt to it. How would the antenna be made to give it this 3
degree downltilt? It stated it also had 20 1/2 waves to it also and
was same length overall.

==========

The question asked was -

"How do you know that Magid has the most rigorous derivation of . . . . . .
".

Of what the derivation was was of no consequence. It was a matter of
judgement of Magid's (or anybody else's) qualifications and authority. What
was the purpose of referring to somebody hardly anybody has ever heard of?

Reg.

Great! Thanks, Roy. I have always wondered about this, because it's not intuitive to me. Eventually, every single strand becomes oxidized over it's entire circumference and length, and that would seem to affect the RF conductivity at the surfaces, but apparently not nearly enough to worry about it.

This is good, because #14 stranded is my preferred wire. Paranoia had led me to use #14 solid enameled the last time I put up an antenna, but it's not as compliant, of course.

Thanks again,

Al W6LX

Source record: 109971

Gee, Reg, if all references had to be by someone you've heard of, we'd be pretty much restricted to Heaviside and Edwards.

The purpose was to let people know that there's a derivation which looks to me to be rigorous and which comes to an interesting conclusion -- the same conclusion I reached some time ago with my own analysis, in fact.

A valid analysis is a valid analysis regardless of who did it. But for anyone who is interested, Magid taught at M.I.T. and Brooklyn Polytechnic Institute. In the introduction, the author states:

"I wish to express my profound indebtedness and thanks to Professors Richard B. Adler, Lan Jen Chu, and Robert M. Fano of the Electrical Engineering Department of M.I.T., both for their continued support and encouragement in this project and for their and their present publisher's (The M.I.T. Press) permission to draw freely on many of their concepts, ideas, and even, in a few cases, some well-chosen words from their abovementioned textbooks. I owe a special debt of gratitude to Professor Chu for the innumerable hours that he unselfishly devoted to assisting me in organizing this book."

I know this is meaningless to you, Reg, since you undoubtedly haven't heard of any of those professors, either, let alone read any of their classic papers. Perhaps you haven't heard of M.I.T., either, or at least disdain it due to its location on the wrong side of the Atlantic. That's fine. Thankfully, good engineering will continue to get done without your approval. If you're interested only in analyses by people you've heard of, that's fine. It's obviously a very short list, so you'll be able to continue to reject just about anything out of hand.

Seeing something written certainly doesn't make it so. But seeing it in a text that's undergone considerable scrutiny by very knowledgeable people makes it worthy, to me, of careful consideration. Certainly it deserves a lot more respect than off-hand comments from people with little constructive or rational to offer. And certainly a lot more than conclusions stated with great fan-fare and authority but not backed up by any development or evidence.

Roy Lewallen, W7EL

Source record: 109972

Ken,
With RG-8 size coax I'd make the diameter of the coils
larger than 2 - 4 inches. A small diameter can make the
center conductor migrate to the 'outside' of the coil and
eventually short out (may take awhile). Something like a
3 pound coffe can makes a good form for RG-8. If you have
to force the bend, the diameter is too small.
If you tune the antenna for 40 meters it won't work as
well on 60 meters. The difference may not be all that much
though. I'd make it resonant on whichever band I planned
to use the most, and then 'put up' with it's performance on
other bands.
Something else you might consider. Extend the antenna the
rest of the way around the building and make it into a loop.
That should give you 80 meters and maybe even 160 meters...

hi, marty. i've got a MKIIG in my camper and use it when
camping...not as often as i'd like. no problems with it at all. it
performs well. i guess the only "complaint' i'd have is trying to
remember all of the functions. but that's a problem with most moden
rigs.

Yes, indeed. The power engineers who have to deal with electronic
power supply loads are quick to realize that sine waves aren't enough
for them. Things have changed in that regard since the 50's. It
became such a problem that there are now requirements for power factor
correction (or more accurately, for a maximum power factor, and
maximum harmonic content).

Cheers,
Tom

Thanks for the good info, Doc!

I made the coil 2-5/8" in diameter after trying to make the coil
on a coffee can and had problems with the lip and ribs of the
can preventing me from removing the finished coil. BTW the
2-5/8" is measured from the center of the coax.

Later I went to rat shack and bought 50' of 2 conductor
speaker wire, cut 10 feet off then added the 40 foot pieces
to my inverted V. It now measures 133'2" long and resonates
at 2.715 mhz. my new little Z11 tuner can easily take it down
the rest of the way to 1.800. If I wanted to I could add more
wire and go completly around the building, ending up with
a 200' loop (guestimate)

For the first time in my ham life I've got a 160 meter cap-
able antenna! I'm looking forward to winter.....

As I'm writing this I'm listening to the 3905 Century Club
net on 40 meters. Man - net control and others are booming
in here!

Also, is conductor migration really an issue with solid
dielectric coax?

No one ever said that Zo is always purely real. But many texts do
approximate it this way. Even the ARRL "bible".

Well, Martin, I use mine in my Semi truck, getting beat up by the Arkansas, Michigan, Pennsylvania, New Mexico, Arizona, and California roads all the time as I roll on delivering freight. It's never let me down once. One comment, though, if you plan on using it while rolling, the narrow SSB filter is almost a MUST. Makes listening through the "tire static" (yes, it really does exist. I have proof.) much easier.

Hi Roy,

"RCW 19.94.150
Standards recognized.
The system of weights and measures in customary use in the United
States and the metric system of weights and measures are jointly
recognized, and either one or both of these systems shall be used
for all commercial purposes in this state. The definitions of
basic units of weight and measure and weights and measures
equivalents, as published by the national institute of standards
and technology or any successor organization, are recognized and
shall govern weighing or measuring instruments or devices used in
commercial activities and other transactions involving weights and
measures within this state."

This is from the state of Washington, I will leave it to you to
research your own particular point of liability in Oregon.

I would add what the IEEE offers into the matter of observing
standards in the development of software and confirming your
disclaimers with:

"The Legal Standard of Professionalism"

"One curious fact from the legal perspective decries a serious
lack: there is no such thing as software malpractice. Why?
A peek into the legal mind provides a disturbing explanation.
There is insufficient evidence to show that programmers
know how to learn from each other, much less from the rest of
the world."

I, for one, could envision you having interest in both, but as I
stated before, I could not see you bothered with the first - seeing

that you have not volunteered any additional details of your trade
aside from software, that stands to good reason.

Ideally the counterpoise should have 3-4 radials per band, sloping down at about a 30-45 deg angle.

3841. Re: Bricks effect in dipole resonance? Help!

Newsgroup: rec.radio.amateur.antenna

Source record: 109985

I'd guess that a brick wall would lower the resonance somewhat (due to the brick's dielectric constant), but not introduce a significant amount of loss. But that's a guess.

What I'd do, of course, is model the antenna with EZNEC (the free demo program would be adequate). That would tell me where the antenna would be resonant without the brick wall. Any major deviation from that could be attributed to the brick wall. Of course, you'd have to include your coil in the model, including its loss if you want to determine the antenna loss, and the feedline to account for its impedance transformation and consequent effect on resonance. To determine the antenna loss I'd look at the bandwidth with EZNEC and compare it to the measured bandwidth -- if the real antenna is considerably broader, there's extra loss from somewhere that's not in the model.

If you don't think it's worth the effort to model, you might just try doubling the distance from the wall and remeasuring. I'm not sure that would be enough to really tell, but if the resonance changes noticeably, then the bricks are having an effect. And if the bandwidth decreases appreciably, then the bricks are contributing loss.

Roy Lewallen, W7EL

"Matthew and Wendy Plante" wrote -
> Is there a significant difference in gain between an
> inverted Vee and a horizontal dipole antenna?
>
==========

Gain is not an appropriate term to use in a performance comparison.

The power radiating efficiency of an inverted-vee is typically 3 to 5 decibels worse than a horizontal half-wave dipole at the same height as the apex of the vee. Less than an S-unit. This is due entirely to extra loss induced in the soil under the antenna, the average height of the wire in a vee being roughly half the height of the dipole.

The radiating pattern of a vee is very little different from a horizontal dipole at the same average height. It is a little more omni-directional which may be considered an advantage. But in practice the difference is not noticeable.

If you took both antennas up to a height of a wavelength above ground there would be no difference between the two.

Installation advice - keep the ends of the vee as high as possible above ground level.

To relate antenna-plus-feedline performance to all dimensions and ground conditions, download in a few seconds and run immediately, program INV_VEE from website below.

Dimensions and angles can be smoothly varied from the keyboard. Optimise performance on what will fit into your backyard.

Wow, thanks for the heads-up. I'll be more careful to specify circuit board trace line widths in furlongs, and volumes of radar detection regions in bushels, those being duly recognized customary units of measure here in Oregon. I'll no longer use lakj;ofs and mapeurqak!pys, which I had previously been using.

As I'm afraid so often happens with your postings, I haven't a clue what you're trying to say. It sounds vaguely like a complaint, but I can't for the life of me fathom what about, except that it seems to be some sort of objection to the legal disclaimers which accompany my software. Could you please try to rephrase it in a way that can be understood by an engineer with a sadly deficient liberal arts education?

If you feel that the legal disclaimers which accompany my software are unduly restrictive or otherwise too onerous for you, or you're not fully satisfied with EZNEC in any way, all you need do is so state in peasant-level plain language so I can understand it, and I'll promptly refund the full purchase price. Just as it says clearly in the EZNEC manual (Help/Contents/Introduction/Guarantee).

Ken:

I've not run HF measurements on bricks, but I can tell you that a brick wall is extremely lossy at 1 GHz and above, by measurement. Their water (dielectric constant = 80) content is relatively high unless recently baked and sealed, and depending on the particular clay they were fired from, they are somewhat conductive. So, placing your antenna close is like putting it next to a high dielectric RF absorber. Not a good choice.

3846. Re: Vee vs. Dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-22 03:41:55 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vkb4844h52sgbf@corp.supernews.com>
Source record: 109989

Since this isn't true except under particular circumstances, I'd hate to see it become an unqualified rule of thumb. For example, here are some values for the total ground loss from an inverted vee and dipole, with the apex of the inverted vee the same as the height of the dipole. Modeling was done at 14 MHz over average ground.

Ht (ft) Inv Vee Dipole
12 5.77 2.05
20 2.08 1.18
30 1.47 1.18
40 1.65 1.4
45 1.72 1.39
50 1.63 1.27

As you can see, the difference is less than 1 dB except for the lowest height.

At an apex height of 12 feet, the ends of the inverted vee were about 2 inches off the ground, so that was as low as it could have been constructed with a 90 degree apex angle. Interestingly, the loss of the inverted vee reached a maximum at 45 feet. The dipole did likewise, at about 40 feet.

I mentioned that an "equivalent height" for a dipole is 1/3 of the way out from the center. This is based on the current distribution, and when a dipole is put at that height, it has about the same elevation pattern as the inverted vee. Putting a dipole at the "equivalent height" of the lowest inverted vee (i.e. 8 foot high dipole) shows 3.55 dB ground loss, still 2 dB greater than the inverted vee at 12 feet.

Scaling for 3.5 MHz shows 4.5 dB for an inverted vee with apex at 48 feet and ends about 9 inches above the ground, vs 1.35 dB for a dipole at 48 feet. So the difference is just slightly less than the corresponding antennas at 14 MHz.

My conclusion is that the rule holds only for antennas very close to the ground. But the actual difference will depend on the frequency and ground charactersitics as well as the inverted vee's apex angle.

Anyone wanting to compare particular antennas can easily do so with EZNEC. The free demo program is adequate. Simply specify Real, High Accuracy ground and a 3D plot. Make sure wire loss is zero and there are no lossy (resistive) loads in the model. Then run the 3D plot and look at the "average gain". It'll represent the total ground loss. For the values above, I used example files BYDipole.EZ and BYVee.EZ. In both models, I changed the ground type to Real, High Accuracy, the ground

description to Average (0.005 S/m conductivity, 13 dielectric constant),
and the plot type to 3D. Height was then changed as required using the
Change Height feature in the Wires Window.

Although this is academically interesting, I don't see any immediate
practical use for the information. It doesn't tell you how strong a
signal your antenna will produce in a given direction, which is usually
what you want to know.

Surely, then, one of the more educated but earthy readers understood it and can translate for me. Anyone? Here it is again in case it was missed the first time:

----- Text to translate:

I would add what the IEEE offers into the matter of observing standards in the development of software and confirming your disclaimers with:

"The Legal Standard of Professionalism"

"One curious fact from the legal perspective decries a serious lack: there is no such thing as software malpractice. Why? A peek into the legal mind provides a disturbing explanation. There is insufficient evidence to show that programmers know how to learn from each other, much less from the rest of the world."

I, for one, could envision you having interest in both, but as I stated before, I could not see you bothered with the first - seeing that you have not volunteered any additional details of your trade aside from software, that stands to good reason.

What's the point? Can someone clue me in?

Hm, woops. My guess that they wouldn't be lossy was based on the assumption that they don't contain much water. In light of what George has said, I retract my guess. Putting your antenna close to anything containing water is bad news from a loss standpoint, as George says.

Our company is *setting up* a lab that will provide an EMC testing service for other companies. We are in Turkey, so I don't think FCC covers here... (and it's not as easy as "drop them from your vendor list", there aren't that many companies or specialists that we can "pick and choose")

I wish someone would answer the question "what would the effect of this mistake be?" If there is no effect, then I'm wasting my (and your) time... Thanks!

> Ideally the counterpoise should have 3-4 radials per band, sloping down at
> about a 30-45 deg angle.

I guess would depend on what you would call ideal, and the freq and
height in wavelength of the antenna. 3 or 4 radials could range from
practically optimum, if at 1/2 wave, to fairly mediocre if the antenna
were for a low band, and the height in wavelength were much below a
1/4 wave. In doing casual testing on this, with pretty much exactly
the same setup, "32 ft whip and sloping radials,", once you drop to a
1/8 wave or lower, 3 or 4 radials is not so hot. Ask Cecil. He will
verify. :) I could easily run my mast up and down to test different
heights. But at 1/4 wave up, the performance starts to approach the
level you'd really expect. "about 50-60 radials worth, if compared to
ground mounted". I ran mine at 36 ft, with four sloping radials. At
that height in wl, 4 radials do pretty well. But I'd need about 8-10
to equal 120 on the ground at 1/4 wave up. The sad part about low
GP's, is as you get lower to the ground, the number of radials needed
jumps quickly by great amounts to keep the same performance. At 1/8
wave up, you need 50-60 radials to equal 4 at 1/2 wave up.
Thats a pretty good incentive to get the antenna as high as you can.
But of course, I'm talking about first rate, dx busting performance.
For lower modes of performance, this will not be as important. But
once you use a good one, you'll never go back. I still miss my 40m GP
late at night. It's laying on the side of my house...Not doing much
good there. It's like an energy free amplifier when working long haul
compared to my dipole at the same appx height. :/ MK

Yes it does exist. I bet the greater bulk of the noise I get at road speeds is tire static. If I stop, even with the engine running, it's pretty quiet. But at highway speeds, my noise will jump up a good bit. I've heard of various cures, ranging from anti-static powder in the tires, to springs you insert in the wheel bearing caps to make a better electrical connection across the bearings I presume. I've never bothered trying any of them yet. I just turn on the NB... MK

Shirley you jest,

Me, a qualified engineer? A futile one perhaps (another clown), but
none here would say qualified. I only do it for work when
prostituting myself with software designing dries up.

Directly or indirectly? Let me count the ways....

I've used a bridge (GR) where the rig was connected as the "unknown"
once (children, this should not be done at home). I keyed down and
made sure the excitation was disconnected (mama di'n't raise no fool).
The results are close at hand, but what the hey, no one here pays any
attention to data anyway. Seems to me with some 10-12A pouring
through the finals, that I came up with (normalized to 50):

Freq. 0Ohms 25Ohms 50Ohms 100Ohms TS430
10 0 0.49ï¿½j0 0.99ï¿½j0 1.96-j0.1 1.48-j1.18
14 0 0.49ï¿½j0 0.99ï¿½j0 1.96-j0.14 1.48+j0.56
18 0 0.49ï¿½j0 0.99ï¿½j0 1.94-j0.19 1.2-j0.11
21 0 0.49ï¿½j0 0.98ï¿½j0 1.94-j0.23 0.74-j0.19
25 0 0.49ï¿½j0 0.96ï¿½j0 1.94-j0.26 0.70-j0.14
28 0 0.49ï¿½j0 0.94ï¿½j0 1.88-j0.28 0.96+j0.56

I've done it by others' methods (enumerated by them here to similar
results as theirs). These results are certainly not as tight (a lot
of reactance) but it sure beats reporting splinters one has gotten
from bench work. ;-)

At first glance it would prove for this strained condition that, yes,
the characteristic Z of the port is NOT 50 Ohms. -Whew!- That was
easy to say. It also says what it WAS, which seems infinitely harder
for many to even speculate.

Hi Abdullah,

That's about the gist of it. Yes, you are wasting your time trying to
obtain that specific answer. For one, you haven't really offered any
data. What is there to answer for? A general yes or no would be
useless as a response.

You have no FCC. A point well taken. But you do have a Standards
Laboratory in Turkey. Consult:
Dr. Huseyin Ugur, Director of National Metrology Institute,
Kocaeli, Turkey
P.O. Box 21 41470 Gebze-Kocaeli Phone: +90 262 643 6093

I am sure they have a list of qualified vendors, and labs performing
your sort of work.

So another way for the lurkers to check all this: assume a line Zo = 50-j5, and a load Zload = 1+j100. Assume some convenient Vf at the load. Calculate rho = Vr/Vf from the equation quoted below. Now find Vr, and from the line impedance and Vf and Vr, find If and Ir. Add the V terms and I terms to get the net line voltage and current at the load. Does that correspond to the expected load current for the given Zload? If so, fine; if not, where does the difference in current come from? If you assume the line current is correct from your If and Ir calcs, and the load current is correct as the net line voltage = net load voltage, and use Zload to get Iload, does the line power dissipation plus the load power dissipation equal the power fed in from a generator? Try all those calcs after revising the Vr/Vf formula to match what Besser is now teaching, and see if things line up a bit better.

The truth is all there to be seen with just a bit of work.

Cheers,
Tom

(yeah, I've done it, as you might guess. And so have a lot of others.)

Back then, Texas A&M was an all-male military military college. We
just didn't have any spare time to spend on trivial subjects. :-)

> me that you are more brilliant than the head of the EE department at
> Texas A&M.

Are you sure you want to discard instantaneous power?

For consistency you will also have to discard:

instantaneous velocity - distance per time
instantaneous current - charge per time. It will be difficult to have
sine waves if the instantaneous current is always 0.
and inumerable other examples

And for consistency, you will also have to toss calculas, the art of
the infinitesimal, which will make solving most engineering problems
significantly more difficult, if not impossible.

Even your oft quoted expression, P = V * I * cos(theta), was derived
using calculus from the instantaneous P(t) = V(t) * I(t).

Are you sure you want to discard all thoughts of the instantaneous?

As to 'the head of the EE department at Texas A&M', he has either
been mis-interpreted or he is wrong. Not wishing to cast aspersions
on his brilliance, I suspect the former.

Well, that expains the wide bandwidth between the 2:1 swr points
(1490 khz)......

Still, I am VERY limited as to my options - I rent here - so this
antenna is it or else I go with a Superantennas MP1 stuck out
the window. While the MP1 is a superb performer for it's size,
I don't think it could do any better than what I've got. Then there
is the fact that I'd have to have the window open to make room
for the MP1 - not a good idea in january in colorado.

Now I haven't had a chance yet to see how good the antenna
works on 160 aside from SWR/bandwith weasuring but tonight
on 80 the antenna seemed to hear pretty well - I'm hearing a lot
of 1, 2, 3 & 6 calls all over the band. If the bricks are absorbing
signals they're not doing too much damage. I'm hearing WWVH
on 5 mhz ok, also and I'm hearing a lot of DX AM broadcast
band stations - It's amazing how crowded that band is at 4 am!

Now I do have the option of taking 1 leg and running it away from the bricks to a nearby tree but the other has to stay where it is - that leg runs most of it's length about 5' away from the wall due to the shape of the building. Problem is that the tree is on the neighbor's property so that's probably out.

Anyways, the performance seems nominal and I don't have many choices so I guess I'll have to be satisfied with what I've got.

Hi People,

I have been looking around at "off the shelf" HF vertical antennas and because of the price I am now considering home building one myself.

The only HF antenna I have at the moment is a half size G5RV so there is room for change ;-)

I guess my main area of interest at the moment is 20m so the vertical antenna would be mainly for that band.

Can anyone point me in the direction of any good home brew designs to save me re-inventing the wheel so to speak?

The antenna can be mounted anywhere from ground level to the top of a 20 ft pole at the bottom of the garden. I will be running upto 100w into it from an FT-920 via it's built in ATU.

Cost is only an issue in as much I begrudge paying £300 + for an off the shelf unit so don't restrict your designs on that front..

I am a bit of a dab hand with the tools too but have no fancy antenna tuning devices, so any design will need to be almost resonant from the off if you see what I mean.

Here is hoping for some good proven designs.

M.

To Bill,
Yeah, I,ts a good idea but they will cost you a bundle. Why not put up a hamstick which performs better than screwdrivers and a good used one will cost only $5-10 the most compared to a $300-500 screwdrivers. You can dedicate each stick to one specific band or put one vice-versa and it is less bulky too!

I have used it on 40 meters successfully and on 15 and 10. The SWR is perfect. The efficiency of the system is not so good. I can do the same thing with my Webster BandSpanner. My biggest problem is being mobile when there is a band opening. Havn't found that many on 15 & 10 recently....at least when I have been in the car.

With the AH-4, it really doesn't matter what I put back on the antenna mount. It will find he L/C combination and match it to the radio (within reason of course...obviously can't use a 1/4 wave UHF spike on 40 meters). I have been looking around for a 102" CB whip. That would work as well as anything.

> Has it not yet occurred to you the impedance of the usual amateur's
> transmitter changes when the load impedance is changed?

[SNIP] Heck Reg! It changes as you modulate! The impedance of my ICOM 746 changes every time I say 'Hello'. It changes from High impedance before 'Hello', to dynamically varying impedance during 'Hello', then back to high impedance as I grab a diet soda.

You are correct in that a constant source impedance exists only in two places: 1) in a perfectly linear amplifier, 2) in our heads as we take exams on circuit theory. All other amplifiers are really non-linear with dynamically varying output impedance.

But it surely uses a lot of bandwidth :-)

Richard's numbers are average for what seems to be the RF component of the waveform. It does not include any variations cause by modulation characteristics.

A single number does not exist!! An average value for my voice characteristics will be different from an average value with your voice characteristics, etc.

The spectral and intensity characteristics of each voice is different and will cause the instantaneous and average V/I ratio in the finals to vary. Therefore, a single number does not exist.

It may be possible to develop an equation with variable functions for spectral and intensity density functions to modulate the output but each solution would be unique.

A nice thevinin model would be a constant voltage, example 12 volts dc, with a dynamically varying source resistor. The source resistor has two components in the modulation scheme: 1) the RF frequency variation, constant frequency, 2) and the second term the audio spectral power density of my voice. This would be loaded by a constant 50 ohm load.

Anyway, it's nice to think about. Averages are much easier to work with though!

Richard Clark wrote:
"I keyed down and made sure the excitation was disconnected---."

Supposing you were measuring the impedance the source shunts its output with, and supposing your amplifier is linear so it can be used for AM and SSB, and supposing that it is Class AB or Class B for more efficiency than Class A, and supposing that it has a small amount of forward bias to reduce crossover distortion, you should measure a much higher impedance while idling than when the transmitter puts full power into a load.

The output impedance has a meaning at maximum power output. This can be determined by trying different loads to find the load that gets the most power from the transmitter. The source impedance is its conjugate.

Best regards, Richard Harrison, KB5WZI

Source record: 109920

Ken,
Migration and solid dialectric insulation, sure, but
it all depends on the diameter of the coil. If you really
wrap the thing tight there's more chance than in a 'looser'
coil. Even in foam dialectric migration isn't a quick thing,
in the solid stuff, it's even slower but it does happen.
Don't count on much performance for your antenna on 160
meters. It may load like crazy, but that doesn't say how it's
efficiency/performance will be. Sort of like a 2" rubber duck
on 2 meters, it works, but not much. But, anything is better
than nothing!
The Century Club is a good place to test how an antenna
works,
lots of stations in all parts of the country. I used to 'live'
on the Century Club when I was working (slow shifts, kept me
from being bored to death).
Good luck with it!
'Doc

"Are you sure you want to discard all thoughts of the instantaneous?

Certainly not, but it has little application to power in transmission line problems.

Power is the rate of transferring energy or the rate of doing work. Electrical power is measured in joules per seconds or more succinctly in watts.

What is the value in watts or joules per second when seconds equal zero? I venture an answer: It is the V x I x cos. theta at that instant, but since work is power x time, it won`t do anything for you in zero seconds.

Best regards, Richard Harrison, KB5WZI

Hi Richard,

And that too was performed, as I described, consistent with others'
reports to their methods (much as you describe).

> 'Doc

You're right about CC - I used to operate a GAP Titan at
my old QTH in Wichita, KS and I NEVER heard anything
beyond the central plains states. Now In Denver I was hearing
stations in So Cal and New Jersey.

As to 160, I'm not expecting much - I may add my leftover
10 foot wires to the antenna and see what happens......

<pause 20 minutes>

Well, just got back in from adding the 2 10' wires... Let's see:

2:1 swr range & resonant freqs:

1.990 - 2.640, 1:1 @ 2.330 mhz (was 2.715)
minor dip to 2:1 @ 8.070 mhz
11.680 - 14.390, 1.2:1 @ 13.610 mhz
21.630 - 25.250, 1.2:1 @ 23.640 mhz

Total antenna length 153'2"

At this point I'm out of wire and really out of room - there
is only 1 point on the far wall where the ends of the antenna
can tied off to and 1 leg is only 5 feet away from it. So, while
I can add 50 feet to one leg to get to that point, I can only
add 5 feet to the other leg. The antenna would not be even
so I'll call it "done".

Thanks all for the tips and advice..... :-)

> What is your definition of a conjugate match? When do you think
> max. power transfer occurs?

I'd be happy to answer this more directly after you show us the steps,
as I suggested, to get from the basic TEM transmission line relations
and the load boundary conditions to Vr/Vf. But for now, I'll let you
consider, if you wish, the case where you have a long transmission
line with reactive Zo, terminated so you have no reflected wave. Rho =
0. SWR = 1:1. I trust you'll agree you "see" an impedance equal to
Zo looking into the source-end of the line. Now imagine that you have
cut this line at some point; you also see Zo looking into that cut,
right? (The side with the load attached, that is.) So, can you
simply connect those two pieces back up and still see no reflection on
the piece on the source side? I _do_ believe that the line can't tell
whether the impedance it's connected to is a load right there, or the
impedance presented by another length of line, so it should be obvious
from that what I believe the line must be connected to, to get rho=0.

Cheers,
Tom

Dr. Slick wrote:
"Does the SWR change as you change the source impedance?"

"SWR" as Reg notes is an indication of match condition when measured at the transmitter output. There may not be enough line for maxima and minima.

Loading a transmitter usually increases the current drawn by the final amplifier. This lowers
its output impedance in most cases. As "SWR" is an indication of mismatch, you can`t change one impedance without changing the "SWR", unless you make a corresponding change in the other impedance in the match. Corresponding is a significant word.

Best regards, Richard Harrison, KB5WZI

If Zeno were around today, he could prove that - based on Cecil's idea
that, as dt goes to zero, energy transfer also goes to zero - there
can be no transfer of energy in a transmission line, since any number
times zero is still zero. Of course, we can all see the fallacy in
that argument, can't we?

I say it would not be, in the specific examples I proposed. Since you say otherwise, prove it. (Hint: if you use the model correctly to calculate the power dissipated in the load and in the line, their sum will be exactly equal to the power supplied to the (load+line). That will be true for any length of line. |rho|>1 doesn't change that.)

Got the correct URL. Interesting config. I notice the antenna is pinned over, looks like either wire or string. If its wire, is that part of the radiating element???

The pic made me think of my first computer/radio setup. It was a Commodore Vic 20 with a Kantronics TU. This was when interfacing computers to radios was the newest thing. I invited a friend to the shack showing him the RTTY and CW capabilities. I tuned into a 20 meter CW QSO. As we sat there watching the message on the screen at 20 wpm, the operator was in an 18-wheeler on the interstate (somewhere). A week later, my friend had a computer hooked to his system.

For 20 meters, all you need is a piece of wire or tubing that's about 16-1/2 feet high (adjust as necessary). I've done it with aluminum tubing (you'll have to use aluminium, of course :)), with a wire hung vertically from a tree, and a wire spaced from a 2 X 4 inch or lighter piece of lumber with TV twinlead standoff insulators. Shouldn't run over ï¿½10 or so, and it will work every bit as well as, or better than, any one you can buy -- on 20 meters. Feed directly with 50 ohm coax. If you mount it at ground level, bury up to a dozen or so wires extending radially outward from the antenna if possible. (I just stretch them along the ground, "stapling" down where necessary with a short piece of wire, and let the grass grow over them.) Make them as long as you can, but there's no point in making them any longer than about 20 feet. If you mount the antenna above ground, you can use fewer radials -- if the base is 20 feet up, four will be plenty. If the radials are above ground, you should make them pretty close to 16 - 1/2 feet long, and adjust if necessary to get an adequately good match.

Roy Lewallen, W7EL

Right, if the question were:
how to optimize the cable length,
Let me suggest the following answer:

****
The correct length of a feed line is from
the antenna jack of your transceiver straight up
to the connector at the antenna feedpoint or balun,
no more no less.

****

Imagine an antenna cable 1 meter too short,
the tranceiver hanging in mid-air above your desk,
otherwise, too long cables tend to cause unecessary
losses and comprise man-traps.

Hope that settles the never ending dispute about
length-of-feedline.
Add some grain of salt :-)

I think you have a slight misconception about the meaning of instantaneous power. AC power is a pseudo-sinusoidal function with respect to time, like that of full-wave rectifier. The function has a value, an instantaneous amplitude, at any time t which represents the rate at which energy in Joules is moving past a point x at time t. It may not be a terribly useful thing to know, but it isn't a ficticious quantity.

Yes.. If you would read the description paragraphs, you would have found out that from the feedpoint of the one 102" whip, to the end of the other 102" whip (insulated from ground) is 40' of wire. it was all part of the radiating element.

I have two unused forty foot lengths of aluminum irrigation tubing I need to unload. One is 4" in diameter and the other is 3" in diameter. Wall thickneses are around 0.060". A number of years ago I built several fullsize 40M yagis for fellow club members and I used this tubing for the booms, etc. I've been storing these "leftover" tubes ever since but now I have to either find a home for them or scrap them. I'll give them away gratis to anyone who will pick them up. The 4" tube would make a nice light-duty easy-up guyed tower for instance. The location is Clifton Heights PA in the southeastern suburbs of Philadelphia. E-mail w3rv to <kelly@dvol.com>

In circuits involving purely sinusoidal V and I of the same frequency, the power waveform is actually a true sinusoidal function, except with a D.C. offset. It doesn't at all resemble the output from a full wave rectifier. The D.C. offset is the average value, and the frequency of the sine portion is twice the frequency of V or I.

Try a 33ft whip, insulated at the base. You could perhaps make this
using an old CB whip on top of your 20ft pole.

This will act as a half-wave vertical on 20m. It requires a matching
network at the base (one L and one C) but only a very modest ground -
just an earth spike would probably do.

However, if you put in some ground radials and adapt the matching
network slightly, you can have a very effective 40m antenna thrown in
free. That will give you something to do on those winter nights when 20m
is closed. No remote band-switching is required - we discussed the
network here a few weeks ago, and someone kindly sent me the scanned
page from QST if you're interested.

Further down the line, save up for a remote ATU, and then all the middle
HF bands - 7, 10, 14 and 18MHz - will be yours with this simple antenna.
It will also get you out on 3.5MHz (where it's rather short) and

21/24/28MHz (where it's rather long, so it loses gain in useless high-angle lobes).

If the pole is at the bottom of the garden, consider beefing-up the top section so that you can string a horizontal wire from the top, back towards the house. With appropriate matching at the base (and again you can do a two-band automatic network) you can make that work on 40 and 80.

The whole thing makes a very useful "progressive" system for the smaller British garden.

Yes, thanks Roy. I've had absolute value circuits on the brain all this
week.

Nevertheless, instantaneous power is simply the instantaneous amplitude
at time t of the (sin^2(wt))/2 function.

Only if the voltage and current are in phase. Here's the more general solution (cosines could be used instead with equal validity):

Given that v = V * sin(wt + phiv)
i = I * sin(wt + phii)

Then p = v * i = VI * sin(wt + phiv) * sin(wt + phii)

The product of the sines can be transformed via a simple trig identity to give

p = VI * 1/2[cos(phiv - phii) - cos(2wt + phiv + phii)]

The first term in the brackets is D.C. -- it's time-independent. The second term is a pure sine wave. So the result is a pure sine wave with a D.C. offset.

I've described the meaning and significance of the power waveform in at least one earlier posting on this newsgroup. If anyone is interested who can't find it on Google, I'll look it up and post the subject and date.

Ken:

With a short attention span, I'm not sure I understand the tree option you mention, but if you can run one leg away from the wall, at near a right angle, then put 2,3, 4 or more wires on the wall and call that your counterpoise. Feed the wire against that. Picture a ground plane turned on its side with the driven element running horizontal. That will get most of the field away from the bricks.

Roy:

I get the impression that building materials survive by being full of water. I had the chance to measure cinder blocks which had been dehydrated (poor RF) and watch them gather moisture over a year or so (really, really bad after a year). And that was inside an air conditioned lab. I suspect the process would have taken only days outside in our 90%+ humidity.

Sheetrock = bad, moisture
Clay tile = better, glazed to prevent moisture penetration
wood = bad, moisture, even after years in 100 degree attics, interestingly enough.
Styrofoam with a thin polymer coating (various proprietary wall systems), = pretty good, unless the interface wicks moisture in because the wrong glue is used.
ad nauseum

>
> Cheers,
> Tom

Hint: the impedance of the generator on the input to a port will
be the same before and after you send the incident wave down the line.

If the reflected RMS voltage is greater than the incident, there
is theoretically greater power in the reflected wave than the
incident. If you get this with a passive network, you have free
energy.

If you can't understand this basic concept, well, i can't help you
then...

Cheers,

Slick

Well, like i said, the SWR will change as you change the source
Z, but you have to measure it before the reflection occurs (the SWR
must be the same Z as the source, and must be right at the output), or
you won't measure it "downstream".

Very interesting.

There's a little data on the RF properties of such things, but it's pretty sparse and limited in scope.

Seems to me that the thing to do would be wind a big air core coil, and measure its inductance and Q. Compare that to the inductance and Q with the material under test inserted into the center of the coil. Given similar size samples, that should at least give an indication of comparitive loss and dielectric constant of the materials. Quantitative results could probably be had with a bit of thought and calculation.

Or maybe just stick a plate on each side of the sample to make a capacitor, and measure the capacitance and Q. One method would probably work better for some materials and the other for others.

There's no doubt that water is really bad stuff at HF.

My only current way to measure SWR is with a bridge and a low
power transmitter. The limit of this device is 5:1. At times, the SWR
inicated 4-4.5:1 but never higher......

I've since added 10' to each leg and here are the latest numbers:

2:1 swr bandwidth and resonance points:
1.990 - 2.640, 1:1 @ 2.330 mhz (was 2.715)
minor dip to 2:1 @ 8.070 mhz
11.680 - 14.390, 1.2:1 @ 13.610 mhz
21.630 - 25.250, 1.2:1 @ 23.640 mhz

Total antenna length 153'2" (76'7" per leg)

>
> Cheers,
> Tom

Contrary to popular belief, you will still have reflections going
from Zo=50-j5 to Zload=50-j5.

This is what impedance matching is all about: getting rid of the
reactance in the line and load, and making sure the resistive
impedances left are equivalent.

Only when Zload=Zo*, will this happen. I.E.: Zo=50-j5 and
Zload=50+j5.

If you plug these into Reflection Coefficient =

(Zload-Zo*)/(Zload-Zo)

Where * indicates conjugate, you will see that the reactances cancel to zero, and the numerator is zero.

This doesn't happen with the regular (Zload-Zo)/(Zload-Zo).

It almost time for me to leave this to others to prove to you, as the communication here is almost non-existant.

Source record: 109871

Ah, thanks for the humor! The last couple days haven't been all that
wonderful, and some levity always helps.

Although there are cosines in Roy's example, I'd like to point out
that t does not stay zero all the time. Gee, surprise. But the
beauty of it is that it works just fine no matter what the waveform.
It doesn't need to be sinusoidal. Life can be easier when we don't
have to deal with differential equations all the time, and for sure we
electronics types have it very easy because our systems are generally
linear enough that we can assume linearity. Then we can take
advantage of things like transforms to resolve an arbitrary waveform
into sinusoids. And we get to sell lots of FFT-based signal analysis
equipment, but please buy more of it.

i=C*dv/dt+v*dC/dt
v=L*di/dt+i*dL/dt
v=i*R
power = v*i
energy = integral(power)dt

If you give me waveforms that are simple sinusoids, then of course my
calcs will have sinusoids in them, and there are a lot of nice
simplifications that leads to so that I can work out the answers in my
head. But the underlying model before the simplifications lets me do
it for any waveform, some easy and some rather difficult.

Cheers,
Tom

You seem to be looking for an argument any way you can, Roy. ;-)
Sin^2(wt)/2 is the general form of any equation with the shape you
described in your previous post. Furthermore, instantaneous power can
be evaluated at any time t, irrespective of relative phase. The point
is simply that instantaneous power isn't necessarily zero as a result of
delta t's approaching zero.

I apologize if my response seemed argumentative. It wasn't intended that way. Certainly, sin^2(wt) has the same shape as the power waveform I derived -- the only difference is its fixed D.C. term. And I certainly agree that letting delta t approaching zero doesn't make any function of t become zero at that point. And just as the analysis I've presented is in your first year college electronics book, so is the point about delta t in everyone's high school or first semester college calculus book. But it's evident that some number of participants in this thread have either forgotten, never seen, or never understood those basic principles. And quite a few people either don't have any textbooks, don't understand them, or are unwilling to open and read them. Hence the postings containing information that you or I could find in moments.

Nope! I'm not one of those tuner-uppers! I have a non-radiating carbon resistor immersed in a gallon of oil inside a metal enclosure.

I adjust my tuner with a whopping 0.02 watts from an MFJ 259B.

Darn INFERNAL Resistance! However it is possible to see the difference caused by bias differences if you have an amplifier. Tune for maximum output. Then reduce drive by 50%. You have to readjust the amplifier for maximum output. [Example there is a difference in tuning between 500 watts and 1000 watts output.]

I used to run a 40M dipole which lay along a rock wall 3 feet
off the ground. I cut it for the center of the band, laid it
out (held in place with a few bricks), and worked the world!

It was just a few bricks short of a full load! Seriously, though,
it worked well.

I have never had a vertical without RFI problems.
Quarter wave, half wave, ground or in the air. Until now.
But......
My BiggIR Fluidmotion vertical is on a 4000 foot metal fence and is about
200 feet from the shack (I live in the country).
So I'm not surprised the alarms don't go off.
I'm about to mount it on the 3500 sq ft Al roof and ground it well.
We shall see,
As far as inexpensive and effective on 20, build a resonant dipole and mount
it however you can.
As high as you can.
If you can go straight up, great.
Coaxial antennas come to mind as well.
You certainly can't beat simple wire antennas for cost-effectiveness.

Radiation angle is essentially the same for both. Mounting it higher will make it more immune to losses from low, nearby objects. An elevated one will also probably receive and deliver less interference -- provided you keep the radials well away from, and not parallel to, mains, telephone, and other wiring.

What about mismatch loss?

Assuming 50 ohm coax, the vee should be closer to 50 ohms.

The 73 ohms of the dipole would result in a small mismatch loss.

One could droop the dipole down about two-thirds along the way to get
close to 50 ohms - at least that's what my EZNEC says - been a user
since the first version.

Um, you should try that in your equation above for Zo=50-j5 and Zload=50-j4. What magnitude rho do you get for that, hmmm?? Oh, this is great fun!
>
> This doesn't happen with the regular (Zload-Zo)/(Zload-Zo).

No, of course that one never gets larger than unity. Nor does it get smaller. It doesn't evaluate well at Zload=Zo, but we might surmise it stays unity there too.
>
> It almost time for me to leave this to others to prove to you, as
> the communication here is almost non-existant.

Seems to be, indeed, though you never know. The lurkers may well have learned a thing or two. The one reference you did post now disavows the form you posted. You've been invited to do some simple math that would show you the truth and you apparently refuse. You are posting any number of ideas contrary to what's easy to show from fundamentals and what's in a large number of published papers and texts and what

has been posted here by many contributors recently and over the years. It's been done with both symbolic math and specific examples. Several inconsistencies demonstrate clearly that Vr/Vf does NOT equal (Zload-Zo*)/(Zload+Zo), and of course most certainly a (Zload-Zo) denominator is going to get you quickly into trouble. The inconsistencies have been pointed out here by me and by others, but apparently you've missed them. I'm sure it's apparent to most lurking where the communications is breaking down. But the formulas you posted above have given me a good laugh tonight, at least! Thanks!

Cheers,
Tom

The loss in the mismatch of 50 to 75 ohms is not worth worring about .

Abdullah:

I appreciate that you are not an EMC expert, nor a top expert in antennas. However, I would expect anyone with a basic electrical engineering, electronics, or physics education to recognize the following: The antenna is not assembled according to any known design. Thus, it will not exhibit performance necessary to conduct and document traceable measurements. Neither the forward gain nor the shape of the pattern is known to the necessary accuracy. Characterizing what amounts to a random collection of metal will be more expensive and time consuming than to simply discard the incorrect antenna and purchase one which is correctly assembled. Will your lab be required to pass an inspection by a National Agency before your measurements will be accepted? With the antenna assembled as you describe, it will not pass inspection.

All of the above comments are based on information which should be available to and known by an undergraduate engineer in any of the several disciplines, and that is the reason for my original comment.

Yes, it is a spot frozen in time, a snapshot of slope at one instant.

What really interests us is average power over a half cycle or more, not instantaneous power, energy`s rate of change, or power`s rate of change.

Agreed. Instantaneous power is real. My point is: Work is power x time.
If time is zero, no work is done.

I checked - 50 ohm to 75 ohm is not a big deal. The SWR is 1.46,
resulting in 14 dB of mismatch loss, which means in a 100W system only
4 watts is reflected back.
So the fact that the Vee is closer to 50 ohms is not a biggie.

Where I grew up and became a ham, there wasn't a lot of money floating around, and most of the hams made do with whatever they could for rigs and antennas. A favorite antenna was a 40 foot length of 4" irrigation pipe, vertical, fed against some ground radials. It works out to very nearly 5/8 wave on 20 meters, and isn't hard to load on 40 and 15. Most of them did quite well with it. Maybe that will give some youngster in your area some ideas. Your free offer is most of what they'd need for that sort of antenna.

Cheers,
Tom

When a fine engineer, with a good education and a distinguished
career, stoops to argue with an anonymous fellow who doesn't
have a firm grasp of even the most basic ideas of wave mechanics,
the result is bound to be a certain amount of frustration. You might
want to ask yourself, Tom, whether Slick is arguing in good faith,
or whether he has other motives.

Is the rate of doing work zero at all instances of time? Nope.
Power is the time rate of change for doing work. It's supposed to be
important to know the formula for finding the instantaneous
rate of doing work so you can ultimately find the average
rate. Maybe you think this is unimportant. I wonder why
textbook authors think it is?

[snip]

After consideration, I must agree with Slick.

Slick is RIGHT and I was WRONG!

Slick please accept my apologies!!! I was wrong, and I admit it!

Indeed, the correct formula for the voltage reflection coefficient "rho"
when computed using a "reference impedance" R, which is say the, perhaps
complex, internal impedance R = r + jx of a generator/source which is loaded
by a perhaps complex load impedance Z = ro + j xo must indeed be:

rho = (Z - conj(R))/(Z + conj(R)) = (Z - r + jx)/(Z + r - jx)

For indeed as Slick pointed out elsewhere in this thread, how else will the
reflected voltage equal zero when the load is a conjugate match to the
generator.

Slick thanks for directing the attention of this "subtlety" to the
newsgroup, and again...

Slick, please accept my apologies, I was too quick to criticize!

Good work, and lots of patience... :-)

Regards,

GEE!!

If dV/dt = 0 then I must have maximum voltage. This has meaning.

Hmmm ... if dP/dt = 0 then I must have maximum 'PEAK' power. This might
have meaning IF I splatter all over the band. But for SWR purposes it
means nothing ... I think ... am I confused?

Let's run a quick calculation as Tom has suggested several times.

Consider a transmission line with Z0 = 50 - j10 ohms connected to a 50 + j0 ohm load. As I hope will be evident, it doesn't matter what's connected to the source end of the line or how long it is. We'll look at the voltage V and current I at a point within the cable, but very, very close to the load end. Conditions are steady state. When numerical V or I is required, assume it's RMS.

I hope we can agree of the following. If not, it's a waste of time to read the rest of the analysis.

1. Vf / If = Z0, where Vf and If are the forward voltage and current respectively.

2. Vr / -Ir = Z0, where Vr and Ir are the reverse voltage and current respectively. The minus sign is due to my using the common definition of positive Ir being toward the load. (If this is too troublesome to anyone, let me know, and I'll rewrite the equations with positive Ir toward the source.)

3. Gv = Vr / Vf, where Gv is the voltage reflection coefficient. This is the usual definition. Likewise,

4. Gi = Ir / If

5. V = Vf + Vr

6. I = If + Ir

Ok so far?

Combine 1 and 2 to get

7. Vf / If = -(Vr / Ir) => Vr / Vf = -(Ir / If)

From 3, 4, and 7,

8. Gv = -Gi

From 3 and 5,

9. V = Vf(1 + Gv)

and similarly from 4 and 6,

10. I = If(1 + Gi)

From 8 and 10,

11. I = If(1 - Gv)

Dividing 9 by 10,

12. V / I = (Vf / If) * [(1 + Gv) / (1 - Gv)]

Combining 12 with 1,

13. V / I = Z0 * [(1 + Gv) / (1 - Gv)]

And finally we have to observe that, by inspection, the voltage V just inside the line has to equal the voltage Vl just outside the line and, by Kirchoff's current law, the current I just inside the line has to equal the current Il just outside the line:

14. Vl = V and Il = I, where Vl and Il are the voltage and current at the load.

From 13 and 14, and noting that Zl = Vl / Il, then,

15. Zl = Z0 * [(1 + Gv) / (1 - Gv)]

Now let's test the formulas for Gv that have been presented. We have three to choose from:

A. The one just posted by Peter, (Zl - Z0conj) / (Zl + Z0conj)

B. Slick's, (Zl - Z0conj) / (Zl + Z0)

C. The one in all my texts and used by practicing engineers, (Zl - Z0) / (Zl + Z0)

We'll plug the numbers into Peter's (A) first, giving us:

Gv = (50 - 50 - j10) / (50 + 50 + j10) = -j10 / (100 + j10) = -0.009901 - j0.09901

Plugging this into the right side of 15, we get:

Zl = 46.15 -j19.23

This obviously isn't correct -- Zl is known to be 50 + j0.

Let's try Slick's (B):

Gv = (50 - 50 - j10) / (50 + 50 - j10) = -j10 / (100 - j10) = 0.009901 - j0.09901

from which we calculate, from 15,

Zl = 48.00 - j20.00

Again, obviously not right.

Finally, using the universally accepted formula (C):

Gv = (50 - 50 + j10) / (50 + 50 - j10) = j10 / (100 - j10) = -0.009901 + j0.09901

from which, from 15, we get

Zl = 50.00 + j0

This is the value we know to be Zl. Getting the correct result for one numerical example does *not* prove that an equation is correct. However, getting an incorrect result for even one numerical example *does* prove that an equation isn't correct. So we can conclude that variations A and B aren't correct.

Actually, the accepted formula (C) can be derived directly from equation 15, so if all the steps to that point are valid, so is the accepted formula.

Why aren't Peter's or Slick's formulas correct? The real reason is that they aren't derived from known principles by an orderly progression of steps like the ones above. There's simply no way to get from known voltage and current relationships to the conjugate equations. They're plucked from thin air. That's simply not adequate or acceptable for scientific or engineering use. (I challenge anyone convinced that either of those equations is correct to present a similar development showing why.)

What about the seemingly sound logic that the accepted formula doesn't work for complex Z0 because it implies that a conjugate match results in a reflection? The formula certainly does imply that. And it's a fact -- a conjugate match guarantees a maximum transfer of power for a given source impedance. But it doesn't guarantee that there will be no reflection. We're used to seeing the two conditions coincide, but that's just because we're used to dealing with a resistive Z0, or at least one that's close enough to resistive that it's a good approximation. The fact that the conditions for zero reflection and for maximum power transfer are different is well known to people accustomed to dealing with transmission lines with complex Z0.

But doesn't having a reflection mean that some power is reflected and doesn't reach the load, reducing the load power from its maximum possible value? As you might know from my postings, I'm very hesitant to deal with power "waves". But what's commonly called forward power doesn't stay constant as the load impedance is changed, nor does the forward voltage. So it turns out that if you adjust the load for a conjugate match, there is indeed reflected voltage, and "reflected power". But the forward voltage and power are greater when the load is Z0conj than when Zl = Z0 and no reflection takes place -- enough greater that maximum power transfer occurs for the conjugate match, with a reflection present.

I'd welcome any corrections to any statements I've made above, any of the equations, or the calculations. The calculations are particularly subject to possible error, so should undergo particular scrutiny. I'll be glad to correct any errors. Anyone who disagrees with the conclusion is invited and encouraged to present a similar development, showing the derivation of the alternate formula and giving numerical results from an example. That's how science, and good engineering, are done. And what it

takes to convince me.

Remember, VSWR does NOT indicate RESONANCE!!!

My 20 meter hamstick on the mobile shows a VSWR of 2.0:1 at resonance!! That is 26 +j0 ohms at 14.225 MHz. Use an antenna analyzer, not VSWR, to determine your antenna resonance. Resonance is the condition of a pure resistive, no reactance, load.

All nearby objects have an impact on antenna performance. The brick wall is obviously adding a significant capacitive load to your antenna.

This might be unrelated. But, when I was having such a problem to get my MkIIG to tune into a UHV-6, I tried everything. All grounds throughout the entire vehicle were meticulously fabricated and tested. Everything looked consistently good/correct/right but I still got SWR's so high that, in certain bands, the radio would shut down. The last thing I did was had a shop weld a $5 ground strap to the frame and bolt to the muffler. My SWR's are fine now.
I can't claim that it was the solution but the SWR miraculously corrected.

I've run the antenna through EZNEC. I didn't include the feedline
coil because I did'nt know how to model it. I'm still learning how
to use the program.

EZNEC not only shows a differant resonance point (3.2:1 @ 9.5 mhz
with Z=19.81 - j 24.27 ohms) but shows a tighter bandwidth.

I can not, however, deny that the antenna works. Again last night
I listened in on the 40 meter 3905 century club net and I was hearing
stations all over. I later moved to WWV @ 5 mhz and heard WWVH
just as strong as WWV (60 miles away).

Now if I could just figure out how to model the 6 turn choke at the
feedpoint..... I'd be happy to e-mail anyone my antenna file if they
would like to modify it. The wires are done and I think I got the feed-
line right but I'm not sure. Then there is the choke - 6 turns of rg8x
@ 2-5/8" dia at the feedpoint with 11 feet of rg8x going from there
to my Z11 tuner.

Any help?

Ken KG0WX

Update: I'm still learning how to use EZNEC but I changed the soil
type to MiniNEC and now show three swr dips, just like the real
antenna. The only differance is EZNEC shows them about 1 mhz
higher and with about 1/4 the bandwidth that I see.....

Must be the bricks.... :-)

> So the fact that the Vee is closer to 50 ohms is not a biggie.
>

Also depending on the height the antenna may not be 75 ohms. I had to put my 80 meter dipole up about 30 feet on each end and the middle is only 20 feet up. I have ran it through the computer program but a graph in an old antenna book shows that an antenna about 20 feet up is closer to 50 ohms than it is to 75 ohms. The swr meter at the end of 100 feet of rg8x showes it to have a swr near 1:1 near the design frequency for what that is worth.

3962. Phase center of patch antenna

Newsgroup: rec.radio.amateur.antenna

Hi,

A question about patch antennas like the one described by K3TZ (http://www.qsl.net/k3tz). What is the distance between the surface of the patch and the center of phase in order to put it at the focal point of a parabolic reflector. Maybe it is not very critical ?

Thanks for your help.

I am looking at W.C. Johnson, pages 15 and 16,
Equations 1.22 through 1.25, where he shows, very
concisely and elegantly, that the reflection
coefficient is zero only when the complex
terminating impedance is identically equal to the
the complex value of Z0.

And not the complex conjugate of Z0.

In other words (read carefully), the complex
terminating impedance whose value is Z0 is

equivalent to an *infinite extension* of the coax
whose complex value is Z0. This is the "clincher".

Observe also the the reflection coefficient for
current is the negative of the reflection
coefficient for voltage.

> that maximum power transfer occurs for the conjugate match, with a
> reflection present.

The "primary" waves are voltage and current, and
the power value involved is
"derived" from the primary waves. Pick a point on
the line and calculate
the instantaneous power at that point. Over time,
that value of power
"travels" along the line in concert with the
voltage and current waves.

There is nothing wrong with this. All of the
hulabaloo over this subject isn't worth a hill of
beans. Everyone understands what power "flow" and
"power outage" mean.

3965. Take off angle

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-23 15:06:38 UTC
From: aunwin@insightbb.com
Message-ID: <85ed38d.0308230706.48804877@posting.google.com>
Source record: 109907

I had always thought that take off angle was
a function purely based on ht over ground
and nothing else.
When experimenting with my AO computor program
on colliear arangements I.E. without booms, I
am finding that the 'Take off' angle becomes lower
with increasing gain over a dipole.
The top edge of the leading lobe stays constant
with that of a single dipole but with the slight
lowering of the lobe angle as much as 1db of
increase in gain are obtainable at the LOWEST angle.
Does anyone know of a text book that discusses the
why's and wherefores of these lower angle gains
together with its 'known' limitations?
Is it possible that it is a parallelogram
resultant of increased vector value versus the
ground influence constant?

One other thing. If the reflection coefficient is
zero, then all of the real power that is dumped
into the coax is being delivered to the load,
minus the losses in the coax. The system is as
good as it can get.

Deacon Dave wrote:
"---am I confused?"

If Dave is confused, I suffer the same confusion. The slope at the maximum of a sine wave is zero. The slope is maximum at zero crossings of an undistorted sine wave.

For the power sine wave, though the fact that a minus times a minus is a plus results in 2x the voltage frequency, dP/dt=0 at maxima.

A question raised in this thread is, how can energy, which is joules per second times seconds, be zero when the number of seconds is zero? The answer seems obvious. Zero times anything is zero.

Roy Lewallen wrote:
"So it turns out that if you adjust the load for a conjugate match,
there is indeed reflected voltage, and reflected power."

Conjugate matching delivers maximum power to the load when a lossless transmission line or network is properly adjusted and inserted between the source and load and when the impedances involved are constants. Nothing is lossless, so the above is true to the extent that the line or network is ideal and the impedances stay constant.

When capacitive and inductive reactances in a circuit cancel, source resistance and load resistance remain. If a loss resistance remains between source and load, it adds to either the source or load, depending on where impedances are determined.

In a true conjugate match, there is no loss between source and load so that the impedances looking in opposite directions anywhere along the line between source and load are conjugates of each other. With a true conjugate match, there`s no reactance, the source and load resistances match, and the stupid transmission line does not know it does not extend forever, so there`s no reflection.

Best regards, Richard Harrison, KB5WZI

That's fine. I agree entirely, and it follows from my analysis and my conclusion. A similar analysis can be found in many texts. My offering to provide a large number of references has brought forth no interest from the most vocal participants, and they've also showed a lack of willingness to work through the simple math themselves. So I felt that it might be a good idea to post the derivation before more converts are made to this religion of proof-by-gut-feel-and-flawed-logic.

I agree with this only in the sense that the "system is as good as it can get" means only that the loss in the coax is minimized for a given delivered power. It doesn't guarantee that the maximum possible power will be delivered to the load.

After some thought, I see I was in error in stating that terminating the line in its complex conjugate necessarily results in the maximum power transfer to the load. If the 50 - j0 had been a source impedance instead of a transmission line impedance, that would be true. However, what results in the maximum power from the source in a system like this is that the *source* be conjugately matched to the impedance seen at the

input of the line. Although terminating the line in its characteristic impedance minimizes the line loss, it doesn't guarantee maximum load power.

Of course, the conjugate matching theorem says that if the line is lossless, a load which is the conjugate of the impedance looking back toward the source from the load will result in a conjugate match at the source and everywhere else along the line, so that will effect maximum power transfer. But the impedance looking back toward the source from the load isn't by any means necessarily equal to the Z0 of the line, so the conjugate of Z0 isn't necessarily the optimum impedance for power transfer, as I erroneously stated. And I don't believe that the conjugate match theorem applies to a lossy line. I certainly don't want to start up an argument about this topic, though, and will simply state for certain that the maximum net power will be delivered to the line when the impedance seen looking into the line is equal to the complex conjugate of the source impedance.

It should be easy to set up a couple of simple numerical examples to illustrate this. Unfortunately, I'm pressed for time at the moment and have to run. I apologize for the error regarding terminating impedance and maximum power transfer.

Thanks for spurring me to re-think the conditions for maximum power transfer. I apologize for the error.

3973. Re: Take off angle

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-23 17:06:04 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vkf7nmhilfgh14@corp.supernews.com>
Source record: 109914

It's really quite simple and fundamental. The "takeoff angle" (elevation angle at which the pattern is maximum) depends on both the height and the free-space vertical pattern of the antenna. Yagis end up having a vertical pattern similar to a dipole in the forward direction because the Yagi provides very little concentration in the elevation plane. Some antennas do provide substantial concentration in the elevation plane, however, such as a W8JK, or collinear as you mention. The elevation patterns of vertically polarized antennas are further modified by the different reflection coefficient encountered by vertically polarized waves.

Kraus has a good discussion of ground reflection coefficient in _Antennas_. The vertical patterns reported by AO and similar programs can be derived by hand from the free space pattern and reflections from the ground using the reflection coefficients derived in Kraus.

Exactly, Bill! And with that, you don't need any equations. You only need to realize that if you cut a line which had no reflection on it, you can weld it back together without introducing reflections (assuming you do a perfect job restoring it to its original state). That should be obvious and easy to grasp even for a math-o-phobe.

And thanks to Roy for taking the trouble to actually go through the algebra and post it. I honestly hoped that S. would do that, and still cling to the belief that there may have been a lurker or two who also did it.

Cheers,
Tom

My working definition for SWR is (1+|rho|)/|(1-|rho|)|. (Note the overall absolute value in the denominator, so it never goes negative.) Rho, of course, is Vr/Vf = (Zload-Zo)/(Zload+Zo), no conjugates. In that way, when |rho|=1, that is, when |Vr|=|Vf|, SWR becomes infinite. When |rho|>1, SWR comes back down, and corresponds _exactly_ to the Vmax/Vmin you would observe _IF_ you could propagate that Vr and Vf without loss to actually establish standing waves you could measure. I agree with Bill that all this is academic, but my working definition seems to me to be consistent with the _concept_ of SWR, and does not require me to be changing horses in mid-stream and remembering when to use a conjugate and when not to. I _NEVER_ use Zo* in finding rho. To me it's not so much a matter of nitpicking an area of no real practical importance as coming up with a firm definition I don't have to second-guess. Except on r.r.a.a., I don't seem to ever get into discussions about such things, but my definitions are easy to state up front so anyone I'm talking with can understand where I'm coming from on them.

> transfer.

Roger to that. In the special case of conjugate
matching generator to load, via a Z0 line, if we
know the generator impedance we can do that. But
for PAs the generator impedance is "who knows
what?" so the best we can do is make the load
equal to the complex Z0. Then forward power is all
there is and reflected power is zero. My Bird
meter then tells me that the calculated VSWR is
1.0:1.0. which is what my PA is designed for.

If my coax gets so lossy that I have to worry
about stuff like this, I will buy new (better) coax.

No need to buy one. In most ham clubs you can find some sucker who owns
one. I own a MFJ 259B for example. :-)

If you live in the Concord NH area you can borrow mine.

Seriously, many people miss use the term 'resonant' when they mean
lowest VSWR. For years I used a non-resonant antenna and a high quality
tuner for 80/75, 40 and 30 meters. True resonance is not a requirement
for an effective antenna. If you can load it, it will radiate.

Hi Ray,
I've a CJ-7 myself and have some good insights for you. If possible, I think you're 100% on the mark for mounting on the light bar. However, consider grounding. Make sure that your light bar's Electrically connected to the windshield frame (typically, the metal screws into the steel windshield frame are good). If it's a multi-piece bar or the type that pivots down, you should remember those junctions. Also, remember that the windshield hinges aren't Electrical connections for a good ground. Since we rarely drop the windshield (I've done it once in 11 years only for maintenance), you could run a wire from an upper screw to the lower on both hinges. Then, there's your antenna selection.
If you're only running VHF/UHF, I'd just buy a good dual-bander. I think diamond makes some good ones that have a fold-over feature for when you run the trails. That hinge is great when the antenna's up but, IMHO, I'd definitely hold it in place when down with something. If you're bouncing around, it'll go flop around til it snaps. You could still just leave it upright permanently if that happened. HF is a different animal for antennas, though.
For an HF antenna, your best bet's mounted behind the spare but consider the grounding issues I mention above. It would be on centerline and out of the way of antenna-hungry limbs and bushes. A little lower, you'll find a good location on a bracket on the rear right corner (I'm not sure if your model has that tire bump stop). It's a little out there for bushes, though.
Finally, there's the rear bumper but as a ham-jeeper you already know about the vehicle as a ground plane and how "height makes right":) The only other advice that I've found with my Jeep is in the hard top.
If you run a hard top, even though it's fiberglass, it can still do a whammy on your antenna system. I just put one on and the rear hatch has a metal frame. Since I mounted my UHV-6 on the rear bumper, the HF performance is trashed when the hatch is open. I tuned the antenna with the hatch closed and noticed that the darned thing is heavily affected with that metal up and next to the radiator. Also, if you tint the glass like mine, that tinting can have, I think it's metal in it. So, it can have an effect as well, however small or big.
There you go. That's my brain dump of many years in a Jeep and on the radio. Let us know how it works out for you and good luck.

==========

YOUR analysis !

Oliver Heaviside worked it all out 120 years back.

For those antagonists who are not willing, or are unable, or are too frightened, or are just too plain lazy to work through the simple ARITHMETIC themselves, download in a few seconds program COAXPAIR from website below and run immediately. It is designed to do exactly the calculations everybody is at war about. (And many more).

Use any ordinary coax with an overal length of 30 dB or more at 1000 Hz (to ensure a nice negative angle of Zo) and terminate the line with its own calculated input impedance = Zo = Ro+jXo. Then terminate the line with its conjugate. Observe what happens to the reflection coefficient, SWR and actual overall loss. Observe what happens as line length is reduced.

Program COAXPAIR (with other transmission line progs) has been sitting there for 2 years or more.

This is ABSOLUTELY WRONG!

The reflection coefficient is zero only when the Zload
is the conjugate of the Zo.

Go look it up in any BASIC RF book!

Wrong. But at least you admit that the "accepted" formula (which
is fine for purely real Zo) implies a reflection.

The absence of reflection is what makes the maximum power
transfer.

> But doesn't having a reflection mean that some power is reflected and

> that maximum power transfer occurs for the conjugate match, with a
> reflection present.
>

?? From a theory point of view, when you cancel series reactances
(canceling inductive with capacitive) the series inductor and
capacitor are
resonant, and will thoeretically have zero impedance, allowing the 50
ohms to feed 50 ohms for max power transfer, WITH THEORETICALLY NO
REFLECTIONS.

Marty,
I had a '706 for about a year in the mobile. It did exactly
what it claimed it would do and isn't a bad radio at all. I had
a problem with the programming, etc., just too 'busy' a radio
for
~me~ to use in the mobile. There were some things that if I
wanted
to change, I had to pull over and stop to do. I also didn't
have
much use for the VHF/UHF sections, just didn't do much up
there.
So, I swapped it for another radio (like I'd had before the
'706).
The '706 is a nice little radio with the emphasis being on
little.
I was really happy with some of it's features, but just too 'fat
fingered' to keep it.
'Doc

this looks like the one that i have seen for both general and ideal lines.
reference Ramo, Whinnery, and VanDuzer "Fields and Waves in Communication
Electronics" table 1.23. This is the best summary of equations for
transmission lines i know of, it lists the general formulas with the R and G
terms, lots of j's, and a bunch of hyperbolics... then it lists the ideal
line (R=G=0) and then also a low loss line approximation that simplifies
away the hyperbolics but keeps the j's.

Roy Lewallen <w7el@eznec.com> wrote in message news:<vkf7nmhilfgh14@corp.supernews.com>...
> It's really quite simple and fundamental.

Appreciate your response Roy, but the fact is the
matter is not simple to me. I am comparing horizontally
polarisation patterns in all cases thus I am having
difficulty with your explanation!
It comes to mind also that an antenna used for listening
(beverage ?) also comprises of stacked collinear
horizontally polarised radiators where the vertical
radiators appears to cancel
themselves out.
So it would appear to be a case where
a beam that is close to the ground (coupled maybe to a
radiator other than the ground) is also capable of
decreasing the TOA even more than such an arrangement
at 1WL height.
Odd that you also brought into the picture the W8JK
antenna that also relies on critical coupling for
its extrorninary gain which you suggest also provides
for a low TOA when compared to the Yagi.
I will have to get the Kraus book from the library
for myself to read and hopefully there will be a
graph of some sort that will outline its advantages
and limitations.
In the mean time I will review VERT radiation patterns
of the examples that I chose in the initial post.
(Assuming that somebody does not come along and
triplicate the same thread) Since I see an advantage for
initial band openings without having to deal with the normal
early demise for stacked antennas that are not coupled.
Best regards
Art

I presume that you wish to include a coax transmission line with a
common mode choke? If so there is a section on a work-around for what
I think you are wanting to do in the EZNEC manual. Look under
Building the Model/Using Transmission Lines/Modeling Coax Cable in
EZNEC's help file.

You'll then model the choke as an impedance on the third wire.

I see no one has taken up the challenge in a while so here goes. If I interpret Tom's question correctly:

100 feet of 50 ohm line with 1 megahertz loss of 2 dB/100 feet and 10 watts fed into it must have a load of 69+j107 ohms for maximum power in the load of 8.418 watts. Line Zo is 50-j17.301 ohms.

Is this correct or shall I join Reg in the 'I ain't got it right' box? :-)

I am familiar with limits. Some make sense and some don't. The impedance,
frequency, and SWR of a transmission line with an SWR doesn't make sense
as V goes to zero and I goes to zero. Any old piece of transmission laying
in the yard has zero volts and zero amps. What is the SWR? What is the
frequency? What is the Z0 of the line?

If delta-t ever gets to zero, time stands still. All you can allow
delta-t to do is to approach zero. Once it reaches zero the ballgame
is over. Limit delta-t to a minimum of a yoctosecond and everything
will be perfectly OK.

[snip]

Easy now boy! You'r almost as bad as me!

It is entirely possible, in fact I know this to be true, that there can be more than one *definition* of "the reflection coefficient". And so... one cannot say definitively that one particular defintion is WRONG.

If the definition of the reflection coefficient is given as rho = (Z - R)/(Z + R) then that's what it is. This particular definition corresponds to the situation which results in rho being null when the unknown Z is equal to the reference impedance R, i.e. an "image match". If the definition is given as rho = (Z - conj(R))/(Z + conj(R)) then rho will be null when the unknown Z is equal to the conjugate of the reference impedance conj(R), i.e. a "conjugate match".

Nothing is WRONG if the definition is first set up to correspond to what the definer is trying to accomplish. And so one has got to take care when making statements about RIGHT ways and WRONG ways to define things. Everyone is entitled to go to hell their own way if they are the onesmaking the definitions. Just as long as no incorrect conclusions are drawn from the definitions. That may occur when folks don't accept or agree on a definition.

OTOH....

Definitions and semantics aside, what we should really be interested in is what is the physical meaning of any particular definition and what are its' practical uses.

Clearly if R is a real constant resistance and contains no reactance for all frequencies [R = r + j0] then the two definitions are equivalent i.e. rho = (Z - R)/(Z + R) = (Z - conj(R))/(Z + conj(R)) since R = conj(R). This is

the situation for most common amateur radio transmsission line problems and so in these simple cases it clearly doesn't matter which definition one takes. But the question of definitions for rho is even broader than that. We amateurs usually only examine a very small class of problems, and there are many more and usually much more interesting and challenging problems that require the use of reflection [scattering] parameters.

Now for broadband problems where the reference impedance R is in general a complex function of frequency, e.g.
R(w) = r(w) + jx(w), one is faced with the problem of creating a definition for rho which will be practical and useful and easy to measure...

For an example of a practical consideration, with R a constant resistance it is easy to manufacture wide ranging reflectometers, like the Bird Model 43 since all it needs inside is a replica of the R, simply a the equivalent of a garden variety 50 Ohm resistor. But if the reference impedance R needs to be a complex function of frequency it is not so easy to design an instrument to measure the reflection coefficient over a broad band. In fact if the reference impedance R(w) = r(w) + jx(w) corresponds to the driving point impedance of a real physical system such as 18,000 feet of telephone line operated over DC to 50MHz, then it can be proved using network synthesis theory that one cannot exactly physically create the conjugate R(w) = r(w) - jx(w) for such a line. How then to make a satisfactory reflectometer for this application? To synthesize the reference impedance for such a "broad band Bird" one would have to be approximated over some narrow band, etc... Not an easy problem...

Actually, under the general so-called Scattering Formalism, the reference impedance can be chosen arbitrarily, and often is, to make the particular physical problem being addressed easy to solve. Within the general Scattering Formalism the so-called port "wave variables" a and b [a is the incident wave and b is the reflected wave] are nothing more than linear combinations of the port "electrical variables" v and i [v is the port voltage and i is the port current]. Thus each port on a network has an electrical vector [v, i]' and a wave vector [a, b]' and these two vectors are related to each other by a simple linear transformation matrix made up of the sometimes arbitrarily chosen reference impedance(s).

For example for the "normal" case we are all used to where r is a fixed constant then... [a, b]' = M [v, i]' where M is the matrix of the transformation. Specifically...

b = v - ri
a = v + ri

and the 2x2 matrix M relating the "waves" to the "electricals" has the first row [1, -r] and second row [1, r], i.e. M is equal to:

|1 -r |
|1 +r|

It is easy to show with simple algebra that this definition of the relation M betweent the waves and the electricals yeilds the common defiintion of the

reflection coefficient rho = b/a = (Z - r)/(Z + r).

The way linear algebraists view this is that the vector of waves a and b is just the vector of electricals rotated and stretched a bit!

In other words the waves are just another way of looking at the electricals.

Or... the waves and the electricals are just different manifestations of the same things, their specific numerical values depend only upon your viewpoint, i.e. what kind of measuring instruements you are using, i.e. voltmeters and ammeters or reflectometers with a particularly chosen reference impedance.

All that said, it should be clear that one can arbitrarily chose the matrix transformation [reference impedance] which relates the waves to the electricals to give you the kinds of wave variables that makes your particular physical problem easy to solve. i.e. it dictates the kind of reflectometer you must use to make the measurements. The Bird Model 43 is only one such instrument and it is useful only for one particular and common kind of narrow band set of problems. For broad band problems one needs an entirely different set of definitions, etc...

And so...

In transmission line problems it us usual to choose the characterisitic impedance Zo of the transmission media to be the reference impedance for the system under examination, but that is certainly not necessary, only convenient. And... if you want a null rho to correspond to a "conjugate match" you must choose the reference impdance in your reflectometer to be the conjugate of the reference impedance of the system under examination, and if you want a null rho to correspond to an "image match" then you must choose the reference impedance in your reflectometer to be identical to the reference impedance of the system under examination.

Every one is entitled to go to hell their own way when defining the wave to electrical variable transformations required to make their measurements and solve their problems and this will result in a variety of definitions for the scattering [reflection] parameters. Nothing more nothing less. Others may not agree with your tools, methodologies and definitions, but just be careful to follow through and be consistent with your definitions, measurements, algebra, and arithmetic and you will always get the right answers.

Thoughts, comments?

Hmm...
If the instruction stated that they shoul;d be assembled
"diagonaly" opposite as opposed to "directly" opposite
I would surmise that they are assembled correctly.
Actualy I see nothing wrong with such an assembly and in
fact have seen a military configuration such as this
where two such antennas were used in V shaped form
where the narrow ends were placed together and enclosing
an approx 30 degree angle, all elements being horizontal.

Yes indeed. I hope no one has interpreted all this as meaning that I believe it has any direct relevance to typical amateur antenna applications. It doesn't. As Bill and quite a few others have stated, the output Z of the PA isn't important at all for our applications. And for nearly any calculation you care to do at HF, the assumption that Z0 is purely real is entirely adequate. The precise Z0 might possibly be important if very precise measurements are being made, but that's not something done by most amateurs.

But there was information posted that's incorrect, even if it's not directly relevant to most of us, and that's what prompted my posting in response.

I'm eagerly awaiting your analysis showing how and why it's wrong. Or simply which of the statements and equations I wrote are incorrect, and what the correct statement or equation should be and why. Or even a simple numerical example that illustrates the relationship between reflection and power transfer.

It appears that there are two groups of readers: those who are convinced by authoritative sounding statements not backed up by any evidence, and those who require a solid basis for believing a statement. The first group I can't help at all. But hopefully I've reached at least some people in the second group.

I've never seen the (voltage) reflection coefficient defined as anything other than the ratio of reflected voltage to forward voltage. Do you have any reputable source that defines it differently? Certainly, that definition is central to the analysis I presented, and leads irrevocably to the generally accepted formula relating it to Z0 and Zl.

This is interesting. But how did it lead you to the equation you
determined must be correct? That is, what definition of reflection
coefficient did you start with, where did you get it, and how did you
get from there to the reflection coefficient equation you presented?

I assume that, consistent with the admonition in the last paragraph of
your posting, you were "careful to follow through and be consistent with
your definitions, measurements, algebra, and arithmetic". It would be
very instructive for us to be able to follow the process you did in
coming to what you feel is the "right answer".

Tam, I hope you don't allow yourself to be pushed around by this bully. Your postings are relevant, welcome, and stand by themselves. There's no need for any of us to justify ourselves to the likes of a person who's too embarrassed and insecure to even reveal his name. What we post is either true or it's not, and its truth doesn't depend on what we have or haven't designed. Questioning a person's credentials is simply a way to deflect attention from the questioner's inability to present a rational counter-argument. And a person who won't even reveal his name demanding that someone else jump through hoops to satisfy his demands for credentials? That's laughable. Sad, but laughable.

Remember too that many brick walls use steel reinforcement, or lots of steel strips to hold them to the frame structure unless we are talking a "real" brick wall which is seldom found in the US in buildings much less than a century old.

I think Reg put it best:

"Dear Dr Slick, it's very easy.

Take a real, long telephone line with Zo = 300 - j250 ohms at 1000 Hz.

Load it with a real resistor of 10 ohms in series with a real
inductance of
40 millihenrys.

The inductance has a reactance of 250 ohms at 1000 Hz.

If you agree with the following formula,

Magnitude of Reflection Coefficient of the load, ZL, relative to line
impedance

= (ZL - Zo) / (ZL + Zo) = 1.865 which exceeds unity,

and has an angle of -59.9 degrees.

The resulting standing waves may also be calculated.

Are you happy now ?"

Reg, G4FGQ

If it were not for Reg pointing out this example, i wouldn't have
researched and corrected my original, "purely real" Zo post with the
more general conjugate Zo formula.

And i researched it because i knew that you cannot have a R.C.
greater than one for a passive network (you can only have a R.C.
greater than one for an active network, which would be a "return gain"
instead of a "return loss"), so i knew that when Zo is complex, my
original post must have been wrong.

Roy, you and i have been slinging mud at each other, but i do
respect the things you have taught me, and i do thank you for deriving
the uV/meter equation for dipoles.

But i want you to know that i'm not doing this for my ego. Didn't i admit that calling antennas "transducers" was a better word than "transformers", albiet 2 transducers make 1 transformer?

I have yet to see you admit that someone else has a point.

Intelligent people can be close-minded, that is for certainly, in which case, their intelligence is blunted.

Who are you to correct my homework? Look it up yourself

It's absolutely the correct formula

For passive circuits, 0<=[rho]<=1,

And strictly speaking: Reflection Coefficient =
(Zl-Zo*)/(Zl+Zo)

Where * indicates conjugate.

> >
> > > C. The one in all my texts and used by practicing engineers, (Zl - Z0) /
> > > (Zl + Z0)
> > >
>

This formula is correct too, but only because most texts assume a
purely real Zo.

F+, and take the whole class again.

s11 is a reflection coefficient that has the special condition that
a2 must be equal zero. When a2 is not equal zero, the s11 reflection
coefficient and the apparent reflection coefficient are not the same.

Thank you. That is, of course, for a two port network. Since we've been talking strictly about a one-port case (I think, anyway), let me rephrase the question. Do you have any reputable source that defines the reflection coefficient for a one-port network as anything other than Vr/Vf.

Although it's not really relevant to the discussion at hand, I believe a valid argument could be made that if a2 isn't equal to zero, then S11 isn't a reflection coefficient at all. It surely isn't the reflection coefficient at port 1, anyway. But it's a point I'll happily concede in lieu of fussing about it.

Ok, I'll try again. To determine the relative field strength at a distant point at an elevation angle of, say 20 degrees, put the antenna at the height you're interested in. Draw a line from the antenna to the ground, at a downward angle of 20 degrees, then reflecting upward, resulting in a ray going upward at an elevation angle of 20 degrees. Draw another line from the antenna at an upward angle of 20 degrees. You now have two parallel lines, a "direct ray" and a "reflected ray". At some distant point, draw a line perpendicular to those rays. Measure the distance from the antenna to the new line via each of the two paths, one direct and the other reflected. You'll be adding these two rays, and the difference between the two paths tells you the relative phases of these two components you'll be adding. For example, if the antenna is a half wavelength high, you'll find that at an elevation angle of 30 degrees, the reflected ray travels exactly one wavelength farther than the direct ray, so the two rays will exactly add in phase. At higher or lower angles, they won't. When adding the two rays, you've also got to factor in the free-space radiation pattern of the antenna to see just how much the antenna is radiating at those angles (say, 20 degrees down and 20 degrees up from horizontal, for the pattern at 20 degrees). In the case of a dipole, the free-space radiation pattern broadside to the antenna is circular, so rays at all angles are equal. Thus, 30 degrees is the "takeoff angle" for a dipole up a half wavelength. You do also have to include a factor for the reflection coefficient of the reflected ray from the ground. But for horizontally polarized waves at moderate to low angles, it's very close to one. (But it's not, for vertically polarized signals, so it should always be computed for vertical antennas.) This is the way that AO, NEC, EZNEC, MININEC, and similar programs compute the elevation pattern.

Now suppose that an antenna has a skinny elevation pattern in free space. The W8JK is an example. At, say, 30 degrees up or down, the signal is weaker than at 20 degrees. So the elevation pattern will be correspondingly stronger than a dipole at 20 degrees relative to 30

degrees. This will lower the "takeoff angle" -- the elevation angle at which the pattern is maximum.

These patterns can be pretty easily created with a calculator and either some trigonometry or graph paper if you have the free-space pattern, but modern programs can do the work for you.

> It comes to mind also that an antenna used for listening

No, the radiation from a Beverage is primarily vertically polarized, off the end.

I dunno. Look at the method I described, and try it on your theoretical antenna to see if that's true or not.

> Odd that you also brought into the picture the W8JK
> antenna that also relies on critical coupling for
> its extrorninary gain which you suggest also provides
> for a low TOA when compared to the Yagi.

Egad, the magical "critical coupling". The W8JK has mutual impedance and coupling between the elements like any other antenna. At 4 or so dB for a couple of elements (if you keep losses down), I wouldn't call its gain "extraordinary", either. It follows the same rules as all other antennas, and its gain and other characteristics can be predicted with great accuracy using the same ordinary methods used for all other antennas.

> I will have to get the Kraus book from the library
> for myself to read and hopefully there will be a

Source record: 109867

Now that the various typo mistakes have been corrected, and putting aside for the moment the name calling and ad hominem arguments, could it be that _both_ sides in this discussion are correct? Camp 'A' says that the reflection coefficient is computed the classical way, without using Zo conjugate, and offers various mathematical proofs and discussions of infinitely long lines. Camp 'B' says the reflection coefficient is computed with Zo* (Zo conjugate) in the numerator, and offers explanations dealing with the conservation of energy and maximum transfer of power.

Both sides may be correct since they are talking about _two different_ meanings for the term "reflection coefficient." One has to do with voltage (or current) traveling waves and the other has to do with power. Quoting two references:

###

From Chipman, "Theory and Problems of Transmission Lines," 1968:

Section 7.1, Reflection coefficient for voltage waves:
[Discussion and math, then] ...
rho = (ZL - Zo) / (ZL + Zo)

Section 7.6, Complex characteristic impedance
[Various mathematical manipulations, then] ... "the maximum possible value for |rho| is found to be 1 + sqrt(2) or about 2.41. ... [T]he principal of conservation of energy is not violated even when the magnitude of the [voltage wave] reflection coefficient exceeds unity."

[then more math, then] ... "The conclusion is somewhat surprising, though inescapable, that a transmission line can be terminated with a [voltage wave] reflection coefficient whose magnitude is as great as 2.41 without there being any implication that the power level of the reflected wave is greater than that of the incident wave."

[then a discussion of a source with internal impedance Zo connected to a line with characteristic impedance also Zo that is terminated with a load of impedance ZL, then] "... more power will be delivered to a terminal load impedance Zo* [conjugate of Zo] that produces a reflected [voltage] wave on the line than to a terminal load impedance Zo that produces no reflected [voltage] wave."

So Chipman states quite clearly that zero reflected voltage wave magnitude does _not_ mean maximum power transfer. On the contrary, maximum power is transferred only when there is a non-zero voltage wave reflection (assuming a complex Zo line). Counter arguments along the lines of "Well that doesn't seem right to me so therefore Chipman

must be wrong" don't carry much weight given Chipman's credentials.

###

From Kurokawa, "Power Waves and the Scattering Matrix," IEEE Transactions on Microwave Theory and Techniques, March 1965:

Section 2, explanation of and mathematical definition of the concept of "power waves," explicitly noted by the author to be distinct from the more commonly discussed voltage and current traveling waves.

Section 3, definition of the reflection coefficient [for power waves]:
s = (ZL - Zo*) / (ZL + Zo)
with a footnote "[Only w]hen Zo is real and positive this is the voltage wave reflection coefficient." Kurokawa takes pains to make it clear that his "s" power wave reflection coefficient is not the same as the (usually rho or Gamma) voltage wave reflection coefficient.

Section 9, comparison with [voltage and current] traveling waves:
"... since the [voltage or current] traveling wave reflection coefficient is given by (ZL - Zo) / (ZL + Zo) [note no conjugate] and the maximum power transfer takes place when ZL=Zo*, ... it is only when there is a certain reflection in terms of [voltage or current] traveling waves that the maximum power is transferred from the line to the load."

So Kurokawa agrees with Chipman concerning the condition for maximum power transfer. Kurokawa also defines two different reflection coefficients, both in the same paper.

[In some of the above quotes I have altered the subscript letter assigned to Z, merely for consistency between the two references.]

###

So, it seems to me, everybody can agree as long as it is understood that there are different meanings for the term "reflection coefficient." One meaning, and its mathematical definition, applies to voltage or current waves. The other, with a slightly different mathematical definition, applies to the power transfer from a line to a load. They are one and the same only when the reactive portion of Zo (Xo) is ignored. It may or may not be acceptable to do so, depending on the attenuation of the line and the frequency. Lossy lines and lower frequencies yield more negative values for the Xo component of Zo.

You can use Reg's COAXPAIR or my TLDetails program to do the math and show concrete examples. Try something like 100 feet of RG-174 at 0.1 MHz, terminated with loads equivalent to Zo and then Zo conjugate, and compare the rho (or SWR) figures versus the power delivered to the load for each case. When the termination equals Zo conjugate, note that the total dB loss is actually _less_ than the matched line loss. As counter intuitive as this may sound, Chipman offers an explanation

on page 139. (And as others are sure to point out, this makes absolutely no difference in practical applications and is of academic interest only.)

Copy of the Kurokawa paper, in pdf format, available on request via private email. I've obtained copies of Chipman, on two separate occasions, from Powell's in Portland.

Thanks for that posting, Dan, and for what looks like a very clear
summary.

Just one point, about that very last word: what are Chipman's
"credentials", really? They are not that he is a well-known[*] textbook
author, college professor, PhD, or anything like that. This discussion
is already way overloaded with personal "credentials" of that kind!

Chipman's true credentials are that he has thought about this subject,
noticed the apparent problem, worked it out, and presented clear,
correct conclusions in a way that other people can follow. Those are the
only credentials that really count.

[*] Well-known to some college students in the USA, perhaps? I'd never
heard of him, but Dan's summary suggests this book might be worth
looking for.

Art Unwin wrote:
"Actually, I see nothing wrong with such an assembly and in fact have seen a military configuration such as this where two such antennas were used in a V shaped form where the narrow ends were placed together and enclosing an approx 30 degree angle."

Such an antenna may be called a pyramidal log-periodic.

A version is included in Kraus on page 398. Its boom-separation angle is 60 degrees.

A pyramidal log periodic is the cover story in the July 1969 "Popular Electronics". This is a construction article beginning on page 27. The author is George Monser. It uses 17 rods on each boom, every rod different from the others on a boom. Separation angle for the booms is also 60 degrees. This antenna covers VHF and UHF TV and FM broadcast bands. It is said to match 300-ohm feedline over the range and produce enough gain for "deep-fringe" color reception.

The longest element (not aligned end-to-end as a dipole) is 115-in. tip to tip, or 1/2-wave at about 51 MHz.

Best regards, Richard Harrison, KB5WZI

obvious...

> Grounding will be easy when I get around to it - I have
> baseboard hot water radiators that I can ground to.

NEVER ground to hot water pipes - ALWAYS use the cold water pipe,
as it goes directly to the earth outside the building. The hot water
pipes are routed through the hot water heater(s) and are NOT a direct
path to ground.

> seconds.

But then instantaneous velocity and instantaneous acceleration won't do anything for you in zero seconds, either. And yet, for example, inertial navigation systems successfully operate by integrating these instantaneous values.

Back to your assertion "but it has little application to power in transmission line problems".

It is certainly true that for RF, average power is of most interest. It is what gets you communicating.

But if you want to understand how things work, exploring the land of the instantaneous is quite valuable. It is instantaneous voltages which make standing waves. It is instantaneous signals which cause distortion in diode demodulators. It is instantaneous voltages and currents which are added and subtracted in Bird wattmeters. It is instantaneous voltages and currents which interact at impedance discontinuities to do all the neat stuff. And it is instantaneous voltages and currents which produce instantaneous power.

But I notice an instantaneous willingness to reject the value of instantaneous power. I suspect this is because the conclusions reached when thinking in terms of instantaneous power are inconsistent with some of your long held beliefs and rather than re-examine these beliefs it is simpler to just reject instantaneous power.

But to reject instantaneous power in a consistent manner, you need to explain why you do not also reject instantaneous velocity, acceleration, current, flow or any of the many other interesting things which are a

derivative with respect to time.

For if we accept the argument "in zero time, no energy can flow" then
we should also accept:
- "in zero time, no charge can flow" -- say bye to instantaneous current
- "in zero time, we can move no distance" -- say bye to instantaneous
velocity
- etc., etc.

When you can't find any fundamental reason that the instantaneousness
of power is different from the instantaneousness of other common
measures like velocity, current, etc., you may wish to return to the
original assertion which caused all this fuss:

Assertion A:
"In a shorted ideal transmission line which has reached steady state,
no energy can cross a voltage or current minimum because
p(t) = v(t) * i(t) and at a voltage or current minimum, the voltage
or current is always zero, so the power is always zero, so there is
no energy flow across a voltage or current minimum."

This conclusion contradicts a commonly held belief:

Belief B:
"that in steady-state, energy is flowing along the transmission line
to the end where it is reflected and travels back to the beginning."

Unless you can find an error in the logic of Assertion A, it would
seem reasonable that you re-assess your acceptance of Belief B.

Assertion A caused me to reject Belief B and the world did not
collapse:
- Bird wattmeters still give useful indications
- ghosts still occur on TVs
- echoes still occur on phone lines
- bidirectional communications still occur on two wire lines
but the simplistic explanations for these phenomena offered by
Belief B need to be re-examined. A better understanding is all
that you stand to gain by discarding Belief B.

"You and Richard Harrison are beginning to sound lke Bishop Berkeley."

We are in good company. Terman says on page 84 of his 1955 opus:
"In these equations Zo = sq rt Z/Y is termed the "characteristic impedance" of the line. In the case of radio-frequency lines, Zo can nearly always be assumed to be a pure resistance, as discussed on page 88."

When Terman says SWR = Emax / Emin, it makes no difference whether you use instantaneous values or rms values, so long as you are consistent, the ratio is the same.

Some complained that nobody provided a trustworthy VSWR related to power. Bird Electronic Corporation does:

VSWR = 1+sq rt (reflected pwr/forward pwr) over 1-sq rt (reflected pwr/forward pwr).

Millions of conversions have proved this VSWR from measured powers relation.

Alternatively, from amplitude modulation, the product of two sine waves produces a sum and difference frequency. When the two sine waves have the
same frequency (as they due for the voltage and current contributing to the power), the result is a double frequency sine wave and a 0 frequency difference which is the DC or average power.

Exactly. And when the voltage or current is always zero, so must be the power.

==========

Quite simple! It's "Imaginary power".

As an experienced electrical engineer you should by now be familiar with imaginary quantities. There's no need for confusion.

Mathematics can't be wrong. Only people can be wrong. Just carry on with the calculations. If you asked a real sensible question then eventually you will obtain a real sensible answer.

A great point however I've tested the system before and after - I
touched various components while transmitting. Before, I would
see a jump or drop in SWR. After, no jump at all.

Based on that rather simple test, I can not assume that it's a
"perfect" ground but I do guess it's "good enough". Besides,
the nearest cold water pipe is 25 feet away.

Thanks for the reminder....

first a couple of truisms:
NEVER say NEVER.
NEVER believe anyone who asserts an ALWAYS.
In the end an easy job is rarely as easy as you first thought.

That being said, NEVER rely on pipes of any kind for safety (either AC or lightning) grounding of equipment, ALWAYS run your own wire to the proper ground rod or electrical service connection as required by electrical codes.

RF "grounds" are another problem. The problem here is to remember that any conductor more than a small fraction of a wavelength will have currents induced in it and thus have a different voltage at one end than the other when exposed to an HF RF field. The real aim here is two fold: First, to provide a low resistance path for 'ground' currents back to the antenna end of the feedline so the currents in the feedline can be properly balanced. Second, to keep all equipment and personel in the antenna field near the same potential to prevent injury and reduce interference.

Keith wrote:
"---you need to explain why you do not reject instantaneous velocity, acceleration, ---."

I don`t reject instantaneous anything including power. Instantaneous power is not particularly useful in working with radio transmission lines.

Like infinity, the infinitesimal is unmeasurable. Like infinity, the infinitesimal is useless in calculations. The idea of the infinitesimal is useful in perceiving targeted values approached as a variable approaches a limit.

A differential "d" is an infinitesimal smaller than a difference. "dy" is the differential of y. "dx" is the differential of x. "dt" is the differential of t. The ratio "dy/dx" is a slope defined at a point and is equal to the limit as x goes to zero of the ratio delta y over delta x.

The basis of differentation is superfluous to this discussion, but Keith asks, why not reject things which are a derivative with respect to time including acceleration.

Acceleration may be a good example. Calculus can give the rate at which a variable varies. On the other hand, it can give a function if the rate of change is given.

Velocity is the variable in acceleration. Assume velocity is increasing and you have a definition of the function. For a given velocity the acceleration can be determined, and for a given acceleration, the velocity can be determined.

My point, repeated again, is that when delta time is zero, no distance is traversed, not that acceleration and velocity are zero.

Power x time = energy. Thast`s how the electric power company calculates your bill. If no time elapses during which power is available, no energy is consumed.

Ha! Great point!

I'm planning on buying a Radio Shack outlet tester (22-141, pg 238 of
the last catalog) - if it shows my outlets are configired properly, I plan
on
running a heavy insulated ground wire from the outlet to the pipe (8").

Does this sound right to you? As far as RF goes, I can touch *any*
component of the system and not see any DC current, SWR or other
changes at all when transmitting so I guess I've got a pretty good RF
ground already.

Then there is the performance issue - the solar numbers haven't been
very good for some time but yesterday I worked stations coast to
coast on 20 & 40 with 5 watts and got some impressive signal reports.
So, whatever I'm doing, it seems to be working OK.

4037. Coaxial coil=choke=problem?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-24 14:38:50 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <mbKdnRmLXY1nUNWiU-KYuA@comcast.com>
Source record: 109680

At my dipole's feedpoint I have a coil of rg8 mini coax
wrapped 6 turns in a 2-5/8" dia circle. I found a program
for calculating coaxial traps for dipoles and here are the
numbers it gave me:

Form diameter 2.375"
Coax diameter 0.242"
Capacitance/ft 25.20pf
Turns 6.000
Coil length 1.45"
Coax length 50.30"
End sensitivity 99.130 khz/inch
Turn sensitivity 257.94 khz/inch
Length/Diameter 0.550
Inductance (L) 2.342 uH
Capacitance (C) 105.620 pF
Reactance (X) 148.90 ohms

The program says this coil is resonant (?) at 10.120 mhz

Now here comes the really dumb question - will this cause
a problem on 30 meters? I seem to hear OK but I've not
yet tried to make any contacts...

My SWR meter indicates a 3:1 SWR there but my nifty
Z11 autotuner tunes it just fine.......

What am I not understanding here?

> coefficient at port 1, anyway.

Actually, it is, Roy. s11 is the *physical* reflection coefficient.
For instance, in the following two-port network:

source---50 ohm feedline---+---1/2WL 150 ohm feedline---50 ohm load

s11 is *defined* as the input reflection coefficient with the output
port terminated by a matched load (ZL=150 ohms sets a2=0). s11
continues to be *defined* as 0.5 even when a2 is not zero.

s11 = (150-50)/(150+50) = 0.5

Since a Z0-match exists at '+', the reflection coefficient on the
50 ohm feedline is zero. rho = Sqrt(Pref/Pfwd)

For a two-port network with a2 not equal to zero, the reflection
coefficient 's11' is NOT equal to the reflection coefficient 'rho'.

The energy analysis on my web page deals only with physical reflection
coefficients. If 'rho' is not a physical reflection coefficient, then
it is the END RESULT of a mathematical calculation and is not the
CAUSE of anything. If a source doesn't "see" a physical impedance
discontinuity, it doesn't "see" anything except forward and reflected
waves. Coherent waves traveling in opposite directions are "unaware" of
each other. Coherent waves traveling in the same direction merge, lose
their separate identies, and become indistinguishable from one another.

If a lossy line is terminated with the complex Z0,
there is no reflection from the load, but the
maximum possible power is not delivered. If the
load is made equal to the complex conjugate of
Z0 the maximum *forward power* is delivered but
there is a reflected power (VSWR is not 1:1).

It is difficult to say that the maximum *power* is
delivered without knowing the generator impedance,
since it is involved in any so-called "conjugate
match". For a lossy line, the idea of conjugate
match is, at best, very approximate anyway. And
generator impedance is a mystery in most, but not
all, transmitter PA situations. One possible
exception: a large amount of negative feedback
helps to determine, to some extent, output
impedance, for a signal with time-varying
amplitude (e.g. SSB).

It seems to me to be clear that the use of Z0* in
the reflection coefficient equation has not been
corroborated (see Roy's post), but the use of
ZL=ZO* has been. The two ideas are not equivalent.

After looking at some examples, using the exact
complex hyperbolic equations with Mathcad, it is
obvious that a line must be very lossy to make a
significant difference whether ZL or ZL* is used
to terminate the line. Still, it is important to

understand the basic principles involved, so this exercise is not foolishness at all.

A word about "credentials". We all respect established and competent authors. But I have noticed on several occasions that blind faith has some exceptions. As an experienced author, I am personally familiar with this problem.

G. Gonzalez (highly respected) "Microwave Transistor Amplifiers" second edition, has a good discussion of Power Waves, based on Kurokawa (I also have his article). There are no transmission lines, and the term ZS* (ZS=generator impedance) is used. In particular, a power wave reflection coefficient is defined:

Gp = (ZL-ZS*)/(ZL+ZS)

which looks quite familiar, with ZS replacing Z0. Also, a voltage reflection coefficient:

Gv = [Zs/Zs*] x [(ZL-ZS*)/(ZL+ZS)]

and a current reflection coefficient

Gv = Gp.

The author also defines two-port scattering parameters in terms of power waves, in which ZS* and ZL* appear.

For the purposes of the present topic, involving transmission lines, it seems best to stay away from power waves, without a lot more studying.

>
> Roy Lewallen, W7EL
[snip]

The definition of the reflection coefficient is dependent upon what you define the "reflected voltage" to be.

Consider the classical bridge circuit for measuring reflection coefficients.

If Z is an unknown load presented to a generator of internal impedance R and that internal impedance R is used as the "reference" impedance to observe/measure the reflected voltage b and that reflected voltage b is calculated/measured by observation of the voltage v across the load Z and the current i through the load Z then the classical definition of a reflected voltage would be calculated as:

b = v - Ri = Zi - Ri = (Z - R)i Volts.

and the incident voltage a would be the Thevinins equivalent voltage across the sum of Z and R, i.e.

a = (Z + R)i

which from the classical definition of the reflection coefficient as the ratio of the reflected to incident voltage as rho = b/a would yeild the usual formula:

rho = b/a = (Z - R)i/(Z + R)i = (Z - R)/(Z+ R).

In which no conjugates appear!

Now if we take the internal/reference impedance R to be complex as R = r + jx then for a "conjugate match" the unknown Z would be the conjugate of the internal/reference impedance and so that would be:

Z = r - jx

Thus the total driving point impedance faced by the incident voltage a would be 2r:

R + Z = r + jx + r - jx = 2r

and the current i through Z would be i = a/2r with the voltage v across Z being v = a/2.

Now the reflected voltage under this conjugate match would not be zero, rather it would be:

b = (Z - R)i = ((r - jx) - (r + jx))i = (r - r -jx -jx)i = -2jxi = -2jxa/2r = -jax/r

and the reflection coefficient value under this conjugate match would be simply:

b/a = rho = - jx/r

Thus I conclude that, under the classical definitions, when one has a "conjugate match" [i.e. maximum power transfer] the reflected voltage and the reflection coefficient are not zero.

Using the classical definitions, the reflected voltage and the reflection coefficient are only zero for an "image match", i.e. when the unknown Z is equal to the internal/reference impedance R and not it's conjugate.

In summary:

Under the classical definition of rho = (Z - R)/(Z + R) rho will be not be zero for a "conjugate match" and in fact there will be a "residual" reflected voltage of -jx/r times the incident voltage at a conjugate match. The only time the classical definition of rho and the reflected voltage is null is for an "image match" when the load equals the reference impedance. [Note some like Cecil call the "image match" the "Zo match".]

And so...

Unless one changes ones definition of the reflected voltage/reflection coefficient to utilize the conjugate of the internal impedance as the "reference" impedance then the reflected voltage is not zero at a conjugate match. End of story.

But, as Slick asked, if one wishes the reflected voltage and reflection coefficient to be zero for a "conjugate match" then one cannot use the "classical" definition of rho = (Z - R)/(Z + R) and instead one would have to use the "alternative" definition of rho = (Z - conj(R))/(Z + conj(R)).

And as I stated in a previous post in this thread, one is free to choose his/her own definition of rho and there is nothing wrong with that as long as one continues to use that consistently.

It's all a matter of perspective and viewpoint. Give me your results for any arbitrary reference impedance and provided you have not done anything inconsistent in your measurements or mathematics then I can readily convert [mathematically] all of your measurements and conclusions into my own

viewpoint and my own reference impedance. Both results will always yeild the same i's and v's only the view of the waves will have changed. As I stated in my earlier posting, the wave vectors are really just another view of the electrical vectors and by setting the reference impedance one is merely changing the matrix transformation that transforms the electrical vectors into the wave vectors. One can then change them again by using another transformation. The only stipulation is that the transformaton be non-singular, i.e. the choice of reference impedance and hence the transformation matrix M that transforms from [v, i] to [a, b] must not be singular.

See anything wrong with this analysis?

No! The scattering paramters, e.g for a two-port the s11, s12, s21 and s22 are all parameters fixed by the network and are not dependent upon either the independent or dependent variables! i.e. b1 = s11*a1 + s12*a2, and b2 = s21*a1 + s22* a2.

> Roy Lewallen, W7EL
[snip]

I followed up with a complete, and I hope simple and easy to follow,
algebraic development in another nearby posting. Have a look and let us
know what you think.

BTW... I don't necessarily agree with Slick's defintition of the reflection
coefficient and for sure, his is not the one I use. But I will defend to
the death his right to use the one he defines, as long as all of his
subsequent calculations and measurements are consistent with that
definition.

Slice and I will always end up with the same voltages v and currents i, it's
just that our wave variables a and b won't agree!

Viewing "waves" is just a viewpoint! One has to view them "through" an
instrument called a reflectometer. When viewed through ammeters and
voltmeters we will all measure the same things.

Only the "electricals" the v and I are "real"! The "waves" the a and b are
just different manifestations of v and i as viewed through and instrument
[reflectometer] using a, perhaps arbitrary, reference impedance, or matrix
transformation.

Sorry Cecil. :-)

Ken:

You haven't constructed a trap. A trap is a parallel resonant circuit, meaning the inductance and capacitance are in parallel with each other. At resonance it presents a high impedance. A trap can be constructed with coaxial cable, but to get the inductance and capacitance in parallel you have to cross connect the inner and outer conductors. See: http://www3.sympatico.ca/wrgraham/ve3etkweb/coaxtraps.html

You have wound the coax into a choke inductor but the capacitance you calculated is between the inner and outer conductors and is not in parallel with the inductance of the windings.

If your calculation of the inductance is correct (2.342 uh), by itself it doesn't have a very high impedance at 10 mhz and doesn't serve very well as a choke. It may be doing more harm than good since a resonant dipole should have better than a 3:1 SWR. Have you tried the dipole without it?

tying the radiator to the electric service neutral probably won't hurt. if the radiator is plumbed with metal pipe and is up to code they are probably tied together somewhere else also. and its always a good idea to be sure your outlets are wired properly, especially in older homes.

if you can touch stuff and not see any changes that probably means that you have a low enough resistance connection back the the feedline point at the antenna. that is where lots of people mess up, they ground the shack end of the coax, but then connect just the center conductor to a random wire or something like that outside. this arrangement forces the return current to flow through ground, the shack equipment, back out the outside of the coax and then back inside the coax to complete the circuit. this causes all sorts of problems like the infamous rf burns from the key or mic, interference to nearby tv, stereo, and computer equipment, etc. even balanced lines and antennas are susceptable to this. if the antenna isn't really balanced (say one leg is near the house the other is in the clear) the unbalance in the return path can cause current to flow back through wiring in the house to get back to the feedline.

with the poor solar conditions right now you are probably doing just fine, just be sure you have a good safety ground and enjoy.

Hi Peter,

One thing: you are expecting everyone to agree that the source has a characteristic Z.

The chasm that separates factions is found in this alone where many who say, no "it is NOT 50 Ohms" (or "it doesn't matter") are loath to come up with an actual value to conjugate (in other words, a sterile position). Such a forced choice leads obviously to the deflation of pet theories. To date their best argument is you cannot possibly know that value (for any of a variety of reasons, unrelated to simply sitting down at the bench and measuring an actual value). In short, institutionalized ignorance, embraced with a mystic missionary zeal, is their crowing logic.

But I do enjoy their examples and logic puzzles reminiscent of the necromancer's formulï¿½ for transmutation of gold into lead. The unrequited dreams would be fulfilled if only the discovery of the Philosopher's Stone could be realized. Hence debate proceeds with the leaps and twirls of zen-cartwheeling.

Hi Keith,

The two statements above are in not about the same thing within the
context of the subject.

The products of two sine waves as you describe are non-linear and are
not found on the Smith Chart, nor in the transmission line. [Except
insofar as it is forced deliberately (and that has yet to be revealed
by any correspondent), or through negligence of line maintenance with
corrosion products and dissimilar metals interfaced.]

> > > path to ground.
> > >
==========

Not entirely correct.

ALWAYS use the cold water pipe.

And if you have a hot water pipe ALWAYS connect that in parallel.

Two connections in parallel ALWAYS have a lower impedance than either of them.

Hot water, wall-mounted, central heating radiators are convenient connecting points.

If you have a gas pipe then make it a three-some.

And of course take advantage of the electricity supply ground via the domestic power wiring.

If there's a 14-gauge wire running from a bedroom shack, through the window, down the outside wall, to a bunch of buried radials in the back yard then include it with the others.

The whole system is just a bunch of random length radials and, up to a break-even point, the more the merrier.

If any one of the principal ground connections can be broken without having any affect on the tuner settings then you've already gone far enough.

But whatever you have there's no guarantee you will be free of RF in the shack. RF comes in through the windows, ceiling, walls, doors and floor of the shack direct from the high-power near-field of the antenna. And you can't criticise the antenna - it's only doing its job.

If in a bedroom, as a last desperate resort, take up the carpet or lino and cover the floor-boards with chicken wire. Re-lay the carpet or lino. Connect the chicken wire from two spaced points to the terminal at the rear of the PA which is marked "Ground".

The dipole resonates (or at least has a 1:1 match) at 2.31 mhz. Without
the coil, I had problems with RF in the shack. A nice fellow changed my
mind from buying a balun to simply winding the coil at the feedpoint.
It seems to have worked. I suppose I could wind more turns to get a
higher inductance - what amount would you advise?

Thanks for your insight as to the differance between my coil and a trap!

Ya learn something new everyday..... :-)

Will there be a significant difference in the performance of two shielded loop antennas (used for receive only) if the only difference between them is that one is made of copper and the other of aluminum? Does one "shield" better than the other? By performance I'm looking at depth of null, SN ratio, or overall gain. Any other comments on choice of material greatly appreciated.

Thank you.

Hi Ken,

Not much reactance overall for one. I've lost track what bands you
want to work, but the SWR would suggest not much Q either. There is
also the matter of how long your cable is too at any particular
wavelength; at some lengths, like half wave, it just doesn't matter if
you had a choke or not (the radiation resistance would snub the
current anyway).

You got 3:1 for any number of reasons, but your tuner took care of it.
That's what a tuner is for. [However, as a solution it is unrelated
to your original problem of a hot coax shield.]

Feeling a little chagrined at accelerating the super glue bond? ;-)

Offhand I would offer that you are probably out of the woods. Just
leave it alone barring repeated symptoms that lead you here.

The problem lies in the difficulty of measuring or
calculating Zs, especially for signals that have
large variations in amplitude, such as SSB.

There is no institutionalized ignorance, just a
lot of skepticism regarding the reliability of the
analysis methods and the measurement methods.

Hi Ian,

Any university student in course work relating to Transmission lines
would have a copy. It comes from a successful line of tutorials known
as "Schaum's Outlines."

Chipman also discusses the relevancy of the characteristic Z of a
source to SWR, which is tucked away in the unread part. ;-)

A coil of coax has capacitance between turns. This makes the coil look like a parallel resonant circuit -- like a trap -- at some frequency. The most effective choke is self resonant at the frequency of use. The diameters and numbers of turns for coax choke baluns given in the _ARRL Antenna Book_ are ones that result in self-resonance at the center of the recommended operating range. These were determined by measurement with a vector impedance meter. An antenna analyzer can be used just as well for measurement of choke impedance, by tying the inner and outer conductors together, connecting one end of the choke to the analyzer "hot" lead and the other to the analyzer ground. The higher the impedance, the better.

Hi Bill,

If the best that skeptics can offer to methods described and data
obtained are "it's not important" or "the time is not justified going
there;" then that is not a particularly high bar of excellence in
reasoning and remains thinly veiled institutionalized ignorance.

Or call it intellectual glaciation, the insurmountable obstacles plea
as argument defending naysaying is frayed and time worn. This is all
"special engineering olympics" caliber justification. Perhaps the
correspondents who enter into these debates should have their
handicaps posted somewhere so the odds makers could weigh the risks of
following such gold medal champions.

Winding the coil at the feedpoint creates a choke, known also as a "current balun". It serves the primary function of a balun which, for coax, is to prevent current flow on the outside of the coax.

As I mentioned in another posting, the most effective choke is one that's self-resonant at the frequency of operation. A typical choke make by winding the wire in a flat coil like a coil of rope is very effective over about three ham bands, if it's resonant at the center of the range.

Increasing the number of turns could make your choke more of less effective, depending on where its self resonance now is compared to your operating frequency.

I have used baking soda as an accelerator for years - works great
everytime. Just don't let the puff of smoke that comes out get into
your nostril membranes or your eyes..... nasty reaction, then!

Winding the coil had several good effects:

1) No more rfi in my PC speakers
2) No more fluctuating SWR readings
3) More consistant (and faster) autotuner action

So, it works - thanks to all the advice I got here (it really
makes me feel like the tech + KB0PWC I started out as),
I've got a viable radiation system.

I'll have to wait for the winter 160m season to see how
well the system gets out on that band - W7EL Roy suggested
I model the antenna on EZNEC and compare the resonance
points and SWR bandwidth. I think (?) I have the program
figgured out and it appears his worry about the bricks in my
building effecting the antenna are somewhat proper.

However, the performance of this antenna in the AM broad-
cast band is SUPERB! I'm hearing stations all over the band

at night, from as far away as Chicago and Los Angeles. So I've got hope the antenna won't be a complete flop on 160.

Last night I worked several of the Ohio QSO party stations on 40 meters with many amazed at my "QRP with a wire" setup..... not to bad from Colorado.....

I am copying a design from the PAC -12 from KA5DVS. Now I am using some different materials but using same design. Using what I had on hand. I calculated his laoding coil for 40M to have about 8.68 uh inductance, so I used some 1/8" tubing I had for lower losses. I calculated my coil for 8.87uh by formulae, as it is 8" long and had a radius of .75" with 37 turns. WHich should all work out. But I put antenna outside and it only has lowest swr at 13.4 MHz or so. What the heck is wrong? It should be good around 7MHz same as other design. I know I must be missing something , but kids are driving me crazy and I can't think! Any help is appreciated, thanks.

============================

And conversely, if you can't get a real answer
which can be confirmed by measurements, or
by other independent calculations, then you
didn't ask a real sensible question in the first
place.

Of what uses do RC and SWR have anyway?

What do you do with these quantities, real or imaginary, when you think you
know what they are. Please do not dash for cover up to microwaves where
values can change places with their conjugates as mysteriously as the
imaginary ghost of Shrodinger's Cat can switch between really dead and
really alive states.

I agree with you if the line is purely real. If it's not, you
have to use the conjugate equation.

additionally, just because it's been published doesn't mean that
it isn't wrong! I have an electromagnetics book that has incorrectly
uses complex Zo with the regular equation.

There is not the slightest detectable difference between copper and aluminum shielded receiving loops except in their mechanical properties and the effects on your bank balance.

If you use the loops outside in uncluttered surroundings you would very likely notice no difference in performance even if you entirely removed both shields to leave only the antenna inner wire or wires. The tuning capacitors would need to be increased in value to compensate for the missing shield capacitance.

For a given loop diameter, receiving sensitivity is increased with thicker wire and fewer turns. A single turn of copper or aluminium self-supporting tube has greatest efficiency just as for a transmitting magloop.

I've got the same paper. It's a bit confusing, because then he
calls

[s]**2 = [(ZL - Zo*) / (ZL + Zo)]**2 the "power reflection
coefficent".

Where if you take the square root to the power reflection
coefficient, you should get the voltage r. c.

So perhaps s = (ZL - Zo*) / (ZL + Zo) really IS the voltage R.
C., even in this paper!

> Section 9, comparison with [voltage and current] traveling waves:
> "... since the [voltage or current] traveling wave reflection
> coefficient is given by (ZL - Zo) / (ZL + Zo) [note no conjugate] and
> the maximum power transfer takes place when ZL=Zo*, ... it is only
> when there is a certain reflection in terms of [voltage or current]
> traveling waves that the maximum power is transferred from the line to
> the load."
>

Perhaps he is confused on this point, because he previously
stated:

"When the matching condition (4) is satisfied , the power
reflection
coefficient becomes zero, as expected."

Condition (4) is the Zl=Zo*, which is also called the conjugate
matched condition for maximum power delivered to the load.

It's only when you have a simultaneous conjugate match with a
transistor, that you get the max gain.

> So Kurokawa agrees with Chipman concerning the condition for maximum
> power transfer. Kurokawa also defines two different reflection
> coefficients, both in the same paper.
>

Again, you failed to mention that he defined:

[s]**2 = [(ZL - Zo*) / (ZL + Zo)]**2 the "power reflection
coefficent".

Note the squares.

Copy of the Kurokawa paper, in pdf format, available on request

Download in a few seconds program MIDLOAD and run immediately.

It will soon tell you where or who is going wrong. Coil length and length
of wire beyond end of coils are fairly critical. It's a good idea to use
thick wire on the coil, or use tube on the higher HF bands.

>
>Does this sound right to you?

I would advise _against_ doing this, for a couple of reasons.

One is that the Radio Shack tester can detect certain forms of mis-wiring, but there's at least one which it cannot detect. This is one in which you have a three-wire outlet, hooked up to a two-wire power feed (one which doesn't actually have a ground), and the installer simply wired the "neutral" and "ground" screws together at the outlet.

To a simple static-voltage-based tester (such as the Radio Shack one appears to be) this outlet will test out as "good" - there will be 120 volts between hot and neutral, 120 between hot and ground, and zero between neutral and ground.

However, this sort of outlet does _not_ provide a true safety ground. If you start drawing a large amount of current through the wire (from this outlet or from another on the same wire), both the "neutral" and "ground" contacts will be pulled several volts away from ground by the I*R losses in the neutral wire. If you've got your equipment chassis "grounded" to this outlet, the chassis will be pulled up away from ground - this could present a shock hazard. Also, you can end up with some portion of the power return current (back to the neutral connector at the breaker box) flowing where you don't want it... through your equipment chassis, your hot-water pipe, your antenna-cable coax braid, etc.

Proper testing for a neutral/ground crossconnection may require physical inspection of the outlet. It can, I think, also be detected by measuring the voltage between the neutral and ground pins at an outlet, while drawing a heavy current (e.g. a 1500-watt space heater) through the other side of that outlet. If the outlet is wired properly, you _should_ see at least a volt or so develop between these two pins - if you don't, it may indicate a neutral/ground crossconnect at that outlet.

The other reason I'd discourage wiring the power-outlet ground to your hot-water-heater pipe, is that the National Electric Code doesn't

permit this. If a short circuit occurs somewhere on this circuit, it would cause your water pipes to carry some of the current back to the house ground, and this could result in a shock hazard for anyone in contact with the pipes (e.g. somebody in a shower or tub).

As I recall, the electrical and plumbing systems really should remain electrically isolated from one another _except_ at a single "bonding" point. This ensures that the plumbing system cannot carry ground-return currents, if a fault occurs in the electrical wiring.

Wash my mouth out for saying critical coupling but having said that
I distinguish critical coupling from mutual coupling by the fact that
in critical coupling you have an INCREASE in current
bAt 4 or so dB for
> a couple of elements (if you keep losses down), I wouldn't call its gain

> "extraordinary", either. It follows the same rules as all other
> antennas, and its gain and other characteristics can be predicted with
> great accuracy using the same ordinary methods used for all other antennas.

Sorry, I don.t see it that way at all. W8JK has the arrangement of
critical coupling evidenced by its high gain that drops off quickly
as the coupling is changed. The increased current or coupling factor
is not evidenced with parasitic elements. I know all do not like to
hear such blasphemy which will create a howl but this is how the
original question came up i,e, critically close coupling between an
oversize
dipole by feeding a small dipole in close proximation which lowered
the TOA of the dipole alone (yes, I added lumped constants to follow
the complex circuit aproach)
> > I will have to get the Kraus book from the library

> Roy Lewallen, W7EL
Thanks for going the extra mile with me Roy and for giving me
the time.
Will still have to lean on the library to get a copy for me to
look at to fill in the spaces especially the circular pattern
maybe I will just lay it down to the "curl" for the moment which will
apply a different "spin" to the subject (Pun intended)
The Sterba antenna I will have to review since I see it as horizontal
ly polarised as in a double zep but my narrow education will have to
be
broadened.
Best regards
Art

4076. Active antenna combiner (transmit & receive), 30-87 MHz

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-24 19:52:04 UTC
From: Stefan Moscibroda <mostefan@gmx.ch>
Message-ID: <3f491711_4@news.bluewin.ch>
Source record: 109720

To save antennas on vehicles, I'm interested in a active transmit/receive antenna combininer. It should
allow to use multiple equipment (e.g. 4 radio systems) on just two antennas (a receiving and transmit
antenna). Frequency range is between 30 MHz and 87 MHz. Maximum power is 50 Watts.
Does somebody know a good product or can give me any hint on this? Thanks a lot!

4077. Re: Placement of elements along boom (EMC)

Yes Richard that is the antenna that I had in mind
What bothers me is that since it is for a lab I see
the antenna being used all,for both horizontal and vertical
radiation emmission measurements, which I surmise would
separate it from horizontally polarised form that is used for HF.
However, since all of the experts have frowned on the offset design,
I like Abdulla am quite interested as to what one should expect
from the offset design that would generate such eyebrow lifting.
Regards
Art

yes, please do note the squares.... and remember, just because

[s]**2 = [(ZL - Zo*) / (ZL + Zo)]**2
does NOT mean that
s = (ZL - Zo*) / (ZL + Zo)

this is the one big trap that all you guys that like to use power in your calculations fall into. just because you know the power doesn't mean that you know squat about the voltage and current on the line. you can not work backwards. that is why it is always better to work with voltage or current waves and then in the end after you have solved all those waves you can always calculate power if you really need to know it.

Keith wrote:
"And when the voltage or current is always zero, so must be the power."

No. When power in each direction is alone measured in each direction, it`s found there`s no variation in intensity at all.along the line.

Standing waves are perceived only by using a sensor which does not discriminate by direction and accepts power traveling in both directions at the same time. There actually is no abatement of power in either direction.

Full power will be measured in either direction by a good directional coupler at any place on the transmission line including the spot showing zero volts or amps at SWR nulls.

A standing wave has almost no effect on power in either direction. Forward and reflected waves pass right through each other without significant effect if there is no impedance discontinuity in the line.

Best regards, Richard Harrison, KB5WZI

How so? Doesn't seem to have any value at all in the field of optics.

> It is instantaneous voltages which make standing waves.

That's a no-brainer.

> It is instantaneous signals which cause distortion in diode
> demodulators.

Please define "instantaneous" for us. I suspect it cannot be what
happens in a dt=0 time slot.

> It is instantaneous voltages and currents which
> are added and subtracted in Bird wattmeters.

But the result is rectified and the maximum value is stored on
a capacitor. By definition, a capacitor cannot accept an instantaneous
value of voltage. If it could, it would be called an inductor. :-)

> It is instantaneous
> voltages and currents which interact at impedance discontinuities to
> do all the neat stuff. And it is instantaneous voltages and currents
> which produce instantaneous power.

There's no question that instantaneous voltages are useful.
Optics, by Hecht has a different opinion of instantaneous power.

> But I notice an instantaneous willingness to reject the value of
> instantaneous power.

Please prove that the human brain is capable of instantaneous willingness. :-)

> But to reject instantaneous power in a consistent manner, you need to
> explain why you do not also reject instantaneous velocity, acceleration,
> current, flow or any of the many other interesting things which are a
> derivative with respect to time.

Some things logically have an instantaneous value, e.g. voltage. Other
instantaneous values do not seem to be related to reality. Let me use
your mind-f__king techniques on you. So you are saying that all instantaneous
values appearing in any math model anywhere have an associated existence
in reality. One thing required by that is that you prove that infinity
actually exists in reality. When you have finished your list of natural
numbers, you can start on the list of transcendentals. A lot of what

you and I do in our minds is just mental masturbation.

> Assertion A:
> "In a shorted ideal transmission line which has reached steady state,

> p(t) = v(t) * i(t) and at a voltage or current minimum, the voltage
> or current is always zero, so the power is always zero, so there is
> no energy flow across a voltage or current minimum."

Assertion B: Since the universe is about 15 billion years older than
our solar system, transmission lines have probably been doing their
thing for billions of years longer than your above statement has existed.

> This conclusion contradicts a commonly held belief:

Yes, and is therefore probably as wrong as can be. There is absolutely
nothing in physics that prohibits energy from flowing across an area
where power is zero. INTERFERING LIGHT BEAMS DO IT ALL THE TIME. It's
called superposition, and when the waves are traveling in opposite
directions while superposing to zero, they have absolutely zero effect
on each other. Sorry about that but you really need to understand what
happens to EM light waves when they interfere. The fact that you have
contradicted a couple of hundred years of physics should be cause for
you to pause and think.

> Belief B:
> "that in steady-state, energy is flowing along the transmission line
> to the end where it is reflected and travels back to the beginning."

Please present a model of how standing waves are possible without forward
waves and reflected waves in a single-source, single feedline, single load
system. Until you do that, you are just, IMHO, blowing smoke.

> Unless you can find an error in the logic of Assertion A, it would
> seem reasonable that you re-assess your acceptance of Belief B.

The error in assertion A is that EM light waves cause power nulls
without having any effect on each other whatsoever. And that's exactly
what happens in a transmission line.

> Assertion A caused me to reject Belief B and the world did not
> collapse:

When you reject the primacy of consciousness in favor of the primacy
of existence, you will understand why your thoughts don't effect reality.
Your thoughts also do not affect much of reality. What happens when you
God-like gurus disagree? - Close to nothing!

When you get through with that, consider what happens if time doesn't
really exist and is simply a model of change invented by the human mind.
What happens when you divorce change from the rotation of the earth?

Not to rain on _your_ parade <g>, but, back then, licensed radio
transmitters were about the only "radiators" you had to contend with.
(Well, maybe not in the 60's -- but, I remember the 50's....)
Oh for the days when you could tune to an unoccupied frequency and
turn both the AF and RF control up to max and listen to the cosmic
background.

I'm sorry, Peter, but you probably misunderstood me. s11 cannot possibly
be the same as 'rho' when a2=100 watts.

s11 = b1/a1 when a2=0.

b1 is equal to something else if a2 is not zero.

rho = Sqrt(Pref/Pfwd)

These do NOT have to be the same values. That's all I was saying.

There's no confusion at all (except here on this newsgroup). The power reflection coefficient is known as the "Reflectance" in optics. The voltage reflection coefficient that we know and love in RF is one of the Fresnel (1788-1827) Equations. In optics, it is known as the "amplitude reflection coefficient", equation 4.34 in _Optics_, 4th edition.

May I suggest that everyone obtain a copy of _Optics_, by Hecht, and contribute to his/her basic understanding of EM waves. Light was detectable eons before RF and thus had an extreme head start. We are presently arguing principles that were already resolved by the end of the 18th century.

The other thing that killed radio and TV DXing is 24 hour stations. I used to do TV DXing from Ohio. Turned the antenna East in the morning, and West at night (when the locals were off). Picked up stuff from New York City to Pueblo Colorado, and London Ontario to Santa Clara Cuba. The long haul was all channels 2 & 3.

Whoa there, David. Give me the the three powers associated with a Z0-match point on a transmission line, and I can give you all the voltages and all the currents including phase, assuming the incident generated forward power wave is at zero degrees. Most ham installations are Z0-matched, and I can tell you everything about amplitude and phase given the three powers, assuming the power reflected from the Z0-match is zero. The values you give me are no problem. I've written a program to solve the equation.

Since the days of Fresnel (1788-1827), this information has been known. To admit that ham radio is 300 years behind the times is pretty sad.

Sadly for ham radio, this fact of physics has been known to man for 300
years. How can a "technical" hobby be 300 years out of date?

Does anyone have a info on the Cushcraft R3. I have acquired one from
a friend who found it at an estate sale.
Cushcraft has nothing on their web site, only a R5 and R7 which look
completely different.

I know an insulator is missng on the base but I'm not surewhat else
might be missing and I have no manual.

Any help would be appreciated.

OTOH, if you want to understand how EM waves work, exploring the discoveries of the past 500 years in the field of optics is quite valuable - discoveries that you have officially discounted when you reject the total knowledge base embodied in the field of optics. Seems my "sin" is pretty small compared to yours. :-)

Hi OM's,
For the IC-706 MkIIG, Icom makes two separate tuners, the AH-4 and the AT-180.
FYI: I run the MkIIG and AT-180 to feed a Comet UHV-6 and the setup is fine.
My curiosity is this. If the AH-4 will tune a non-resonant antenna system, why then wouldn't I prefer it over the AT-180 which is used with a resonant antenna. Couldn't I use the AH-4 with an antenna whether it was resonant or not? Or, is there added benefit of the AT-180?

The AH-4 is designed for random wire type antennas. The radiator is attached to the AH-4 via a wire post (as is the ground wire).

4101. Re: Grounding question - this is wierd.....

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-25 00:41:18 UTC
From: Reg Edwards <g4fgq.regp@btinternet.com>
Message-ID: <biblve$dp1$1@hercules.btinternet.com>
Source record: 109744

The previous posting, of course, applies to RF grounding of the radio shack, particularly to end-fed antennas where at some frequencies there may be appreciable RF currents flowing from the shack down to ground via the very uncritical arrangements previously described.

If there are any local or national regulations to be complied with regarding the domestic power frequency safety ground then they should be complied with. But in general such regulations, by themselves, will fall far short of an adequate radio ground.

For example, a single safety ground rod, wherever it is located, will likely have a resistance at all frequencies greater than 50 ohms plus the important inductive reactance of all the wire between the shack and the rod. By all means include the rod in the station's RF ground system but it will be found to be amongst the ground connections which can be disconnected without having any effect on station operation such as tuner settings.

A single rod is no better than a buried horizontal radial wire of the same length. If a rod is the only RF ground available an endfed antenna will work in some poor fashion, RF in the shack, etc., unless the local soil is saturated with salt water - an unlikely condition.

To protect the family home from direct lightning strikes on the antenna then the mast etc., is best provided with its own ground electrode system. We have very few thunder storms in the UK. In all my years I have seen only one lightning strike which hit the ground. So what I have done when a storm seemed imminent (the tuner capacitor sparking over) is just disconnect the antenna at the lead-in to the shack and toss the loose end of the wire as far as I can along the back yard.

For antenna + mast grounding details I leave to more experienced people.

Cecil, email me privately and i will send you the paper. He calls
the voltage reflection coefficient the "power wave reflection
coefficient". And then squares this to get the "power reflection
coefficient".

It's really a bad nomenclature, and no wonder there is confusion.

yes, but he does say that s = (ZL - Zo*) / (ZL + Zo) , first.

But he foolishly calls it a "power wave R. C."

Then he squares the magnitudes [s]**2 = [(ZL - Zo*) / (ZL +
Zo)]**2

And calls this the "power R. C."

The bottom label is fine, we've all see this before, as the ratio
of the RMS incident and reflected voltages, when squared, should give
you the ratio of the average incident and reflected powers, or the
power R. C.

But to call the voltage reflection coefficient a "power wave R.
C."
is really foolish, IMO.

I've been getting careless with my fast typing, i will admit, so
i'm gonna slow down a bit.

I got my B. S. engineering degree at U. C. Davis. What about
you?

I got hooked into broadcast engineering specifically and RF
generally as soon as i graduated.

This shows you how close-minded people like you can be, when you
tell then you can paint and play guitar too. Actually, LOTS of
engineers ARE musically inclined. The best ones really... :)

Some of my job responsibilities for the past 10 years include:

Design, development and test of circuit and board level RF designs
including impedance matching networks (simulating on MIMP) for E-PHEMT
power amplifiers for the GSM, DCS, and PCS cellular bands
(880MHz-1900MHz). Simulations on ADS to assess manufacturability and
robustness. Bias tuning for EDGE mode EVM and Adjacent channel power.
Optimize circuit design and board layout for PAE, gain flatness,
stability under mismatched loads, receive-band noise, AM to PM, input
VSWR and harmonic suppression.
Design and construction of FM stereo multiplexed Phase Locked
Loop transmitters, broadband design (88-108MHz). Design and selection
of VCOs, pre-scalers, and loop filters. Antenna design and
construction: 5/8ths vertical groundplane, 1/4 wavelength, and
dipoles. Compressor-limiter and Chebychev Low-pass filter design.
Microwave (MMIC) testing and tuning (2-18GHz). Design of
equalizers and filters. Linearity of Detector Logarithmic Video
Amplifiers. Temperature compensation networks.

You win a prize if you can guess where i last worked...

Your turn Tom...

Dunno, but the Fresnel Equation for the amplitude reflection coefficient,
assuming normal incidence, is the reflected electric field divided by
the incident electric field. Reckon your great, great, great, great,
great, great, great, great grandfather knew that along with Fresnel?

I agree, it is bad nomenclature. He should have called it the amplitude
or voltage reflection coefficient, the square of which is the power
reflection coefficient.

Source record: 109761

Corrections:

The *magnitude* of the reflection coefficient for horizontally polarized waves is very close to one. But the angle is 180 degrees. That is, there's a phase reversal when the wave reflects. I was also incorrect in saying that the difference in distances for a 30 degree elevation angle for the half wave high antenna is exactly a wavelength. The distance from the antenna to the reflection point is one wavelength, but the difference in distances the rays travel to a distant point is exactly 1/2 wavelength. This can be seen by drawing a line perpendicular to the direct and reflected rays as I suggested in my earlier posting, and looking at the total distances traveled by both rays from their intersection with it. Combined with the phase reversal, the 1/2 wavelength difference in distances results in complete reinforcement at a distant point.

I apologize for the errors. Many thanks to John Farr for reminding me of the phase reversal of the reflection.

Big.

About 1429 times larger than the one for 10GHz that was published in
'Ham Radio' some years ago. Fresnel optics (either concentric refractive
rings or concentric apertures) works perfectly well at RF wavelengths.

So as I try to understand the error in my logic, you are saying that
there can be power, even though the voltage or current is always 0.

In other words, the expression p(t) = v(t) * i(t) does not always
hold and sometimes when v or i is zero, there is power.

Further exploring my error, is this because p(t) = v(t) * i(t) is
not an expression for power or is it that it only holds under
certain conditions?

With a time varying voltage, for each time t there is a particular
value of voltage. This voltage can be called the instantaneous voltage
to make it clear that it is not the average or RMS or peak or any
of the other voltages which may be of interest with regards to the
signal. Hence the notation v(t) representing the voltage at any
time t.

None the less, the original additions and subtractions of voltages
and currents must be done with the instantaneous values for the
proper results to be obtained.

> in reality.

Absolutely not. But I have asked that if you wish to contend that
instantaneous power is of no use while instantaneous current is, that
some rationale be provided. The previous arguments were that it made
no sense because when dt was 0, there was no power. This seemed a weak
argument since a similar argument could be made for the other
instantaneous
value which do seem to be accepted.

Does this non-sequitor mean that you accept Assertion A and wish to
deflect the discussion?

> > This conclusion contradicts a commonly held belief:
>
> Yes, and is therefore probably as wrong as can be.

Perhaps, but I observe that you have not yet pointed out the flaw.
Were you to find the flaw in the logic, I would willingly accept
it as false. Merely that the result disagrees with Belief B is
not, by itself, a flaw.

> There is absolutely
> nothing in physics that prohibits energy from flowing across an area
> where power is zero.

I had always understood that power was defined as the rate of energy
flow. If the power is zero, then by definition, there is no flow.
Perhaps your definition of power is different and we should resolve
that before proceeding.

> > Belief B:
> > "that in steady-state, energy is flowing along the transmission line
> > to the end where it is reflected and travels back to the beginning."
>
> Please present a model of how standing waves are possible without forward
> waves and reflected waves in a single-source, single feedline, single load
> system.

Well, as you agreed near the start of this post (with your statement
"That's a no brainer), it is voltage waves which produce standing waves,
not waves of energy. So Assertion A is not in conflict at all with
standing waves.

> Until you do that, you are just, IMHO, blowing smoke.

It is certainly possible that I have made an error in Assertion A. I
observe that you have not yet located that error. But Assertion A
is fairly short and based on the most basic of concepts. It should
be easy to locate and describe the error, if one exists.

Take a look at a light interference pattern. The minimum irradiance
(power) is I1 + I2 - 2*Sqrt(I1*I2). This is called total destructive
interference, i.e. zero power. Yet those two light beams don't even
know each other is there. Their individual power flows are a constant
amplitude and constant direction.

Exactly the same thing holds true for forward and reflected waves. The
"zero power" points are simply the total destructive interference points.
The forward wave is unaffected by the reflected wave and vice versa.
A physical impedance discontinuity is required to cause interaction
between the forward waves and reflected waves. There is no physical
impedance discontinuity at an SWR voltage node in a constant Z0 feedline.

Which implies that (t2 - t1) cannot be zero because that would
make (tn - t1) also zero. So I repeat, power cannot exist if
dt=0.

> The previous arguments were that it made
> no sense because when dt was 0, there was no power. This seemed a weak

Not a weak argument at all. I think we agreed above that dt=(t2-t1)
is never zero.

> Does this non-sequitor mean that you accept Assertion A and wish to
> deflect the discussion?

Have you stopped beating your wife? See, I can do it also. Please
stop basing your false assertions on NET power and look at the
component energy flowing without effect upon each other.

> Perhaps, but I observe that you have not yet pointed out the flaw.

Observe again. Please reference _Optics_, by Hecht, Chapter 9,
"Interference". You key to understanding will lie in the understanding
of total destructive interference.

> I had always understood that power was defined as the rate of energy
> flow. If the power is zero, then by definition, there is no flow.

There is no NET power and no NET energy flow. There is plenty of
component power and component energy flow. You accuse me of dismissing
"instantaneous power" when you are dismissing a very large portion
of EM physics embodied in the works of Kepler, Descartes, Newton,
Huygens, Fresnel, Maxwell, and Einstein.

Please read up on "total destructive interference" before we continue.

> Well, as you agreed near the start of this post (with your statement
> "That's a no brainer), it is voltage waves which produce standing waves,
> not waves of energy.

So you are saying that voltages waves can exist without energy?
Can voltage waves exist without current waves?

> It is certainly possible that I have made an error in Assertion A. I
> observe that you have not yet located that error.

Of course, I have located the error. You simply do not understand
"total destructive interference" between two waves unaffected by
each other.

> Please go through each of the steps of Assertion A and describe the
> first one which is in error and why.

An SWR voltage (or current) node is the result of total destructive
interference between two waves traveling in opposite directions. Those
two waves have no effect on each other. Your error is in assuming
something about reality based on NET power instead of understanding
the component powers involved in total destructive interference.

And since the power reflection coefficient (Reflectance) is simply the
square of the voltage (amplitude) reflection coefficient, presumably
neither would it. There is no conjugate in these equations in the field
of optics.

(Agreeing with Keith...) Of course there MUST be instantaneous power,
because if there is not, then one cannot find energy by taking the
integral of power over time. The instantaneous value may be zero, or
positive, or negative, of course. Or perhaps another way to look at
it is that if energy, which itself is a function of time, is
differentiable, then power must take on instantaneous values.

Cheers,
Tom

Roy all of this has peaked up a new interest for me
when it appears that all already knew of this in detail.
I am still having diffriculty in reconciling it via AO
programming where vertical, cw and ccw radiation fields
now comes into being.(the relative patterns cannot be
overlaid as can std horizontal patterns)
I came across a rather large article on this matter in Radcom
March '98 (Ala Antenna topicss publication from the RSGB)
which was sparked off by our old friend Lew McCoy,
where it gives further insights to Moxon's statement regarding
the use of a two element instead of a three element with a
adjustment in height. Probably jumping the gun but I ponder
the fact that this subject may well be related to the yagi/quad
debate but for now I have to read and reread what I have including
your comments until it becomes locked and intuitive.
Thanks again.
And now back to conjugate matching, reflections
and the like which have the interests of all (other than myself)
Regards
Art

I'll amplify a little on what Danny said.

If you want to see if the choke is doing its job of reducing feedline radiation, then you have to include both it and the feedline in the model, as Danny described. But you do have to include the outside of the feedline (as described in the manual) all the way from the antenna to the rig, then another wire or wires from the rig to Earth ground. The reason is that this path is part of the radiating structure, if the choke isn't doing its job. You'll also have to know either the impedance of the choke at each frequency or at least band of interest, or its equivalent L and C. If you're using the dimensions of the air wound chokes in the ARRL Handbook near the center of its recommended range, a value of 1000 + j0 ohms is a good working number.

Alternatively, you can assume that the choke is doing its job, and that the feedline radiation is negligible. If you do that, you can put the source at the feedpoint and not include the transmission line or choke in the model. Or, if you're interested in including the impedance transformation of the line in your model, you can use the EZNEC transmission line model to represent it, assuming that the choke is doing its job and the line isn't radiating. In that case, you need to include the length of the line which is wound into a choke, but any effect of the choke itself. When you use the transmission line model, you're modeling the inside of the coax only, and winding the line into a choke has no effect on the inside.

I don't think there is any argument over whether it exists in the math
model or not. My argument is that the concept lacks a lot of usefulness.

"> I can not, however, deny that the antenna works."

"Works" is a binary quantity, with only two values. If we divide antennas up into only the two categories of "works" and "doesn't work", I could simplify the EZNEC output a tremendous amount. It would go through all its calculations, then either turn the screen red or green, and that's all the information you'd need. Sounds like your antenna already "works", so what's left to do?

Seriously, if all you want to do is listen to signals, nearly any antenna will "work". At HF, it can be very small and very, very inefficient, and you'll still hear just as many signals as somebody with a big, efficient antenna. I can hear plenty of DX with my tiny Sony radio and its 18" or so whip. So if listening is your goal, any more fussing around you do with the antenna is a waste of time.

But getting them to hear you is another matter entirely. If that's your goal, then effort spent in understanding your antenna is worthwhile, because it will lead the way to improving it.

If you want EZNEC to tell you what the antenna will do, you've got to describe the antenna accurately to EZNEC. In another posting I just made, I suggested three approaches you can take to deal with the feedpoint choke. Hopefully one of them will give you enough information to answer your questions about the antenna.

I've since made several 6 land, 2 land and 8 land contacts on 20 & 40
with good signal reports. And that was with SF=110 A=45 & K=3!
One contact late saturday night in NJ on 40 was shocked at my antenna
setup - He strongly advised me not to change anything! Not that I could,
even if I wanted to....

I must be doing something right with my itty bitty 4 watts.......

Thanks for all the help.... :-)

Incorrect. You need the conjugate in the numerator if the Zo is
complex. If it is purely real, WHICH MOST TEXTS ASSUME, then you can
use the normal equation.

Look here:

http://www.zzmatch.com/lcn.html

And look up Les Besser's notes on the Fundamentals of RF.

sorry, the derivation for the table in the book i sent before is for the
general case of a complex Zo. they then go on to simplify for an ideal line
and for a nearly ideal line... nowhere does a conjugate show up.

and that reference you give is not for a load on a transmission line, it is
talking about a generator supplying power to a load... a completely
different animal.

Ah, I see. Well, consider this: the concept IS useful to me. That's
not an arguable point, as I am the only one who can evaluate it. If
it isn't to you, you don't have to use it. I'll not argue with that.

Cheers,
Tom

No one from "Camp B" has given any justification for the assumption that the condition for minimum reflection is the condition for maximum power transfer. We're lacking either a proof, a derivation from known principles, or even a numerical example. I maintain that this assumption is false.

Likewise, there's no evidence that the conventional and universally accepted (within the professional community) formula for reflection coefficient violates the conservation of energy. If it did, it would have been shown to be in error long ago.

> Both sides may be correct since they are talking about _two different_

Perhaps. Yet both groups have used it as though it's a voltage reflection coefficient, and as justification for statements made about the reflection of voltage waves.

If people want to argue about the reflection of power waves, I'll gladly bow out and let Cecil and his colleagues resume their interminable arguments without me. If anyone wants to discuss voltage or current waves, I'll try to continue to contribute, as long I don't have to deal with Slick and the insults he uses in place of supporting evidence.

I suggest that those who are using "reflection coefficient" as meaning the ratio of reflected to forward power so state, and restrict their conclusions dervived from it to power waves.

[snip]

I did just that in a separate posting on this thread a couple of days ago.

In fact I "proved" in that post, using basic algebra, that maximum power transfer [i.e. a
conjugate match] does not result in a null in the classical voltage reflection
coefficient. One only get's a null in the classic reflection coefficient if one has
an "image match", i.e. a Zo match to use Cecil's favorite name for that old term.

I believe that "Mother Nature's" voltage reflection coefficient is the well known
classical one, i.e.

rho = (Z - Zo)/(Z + Zo) is "Mother Nature's" reflection coefficient.

Simply because it corresponds to the "image match", i.e. rho will be null when Z = Zo [Not conj(Zo)], and is the condition for there to be no reflected voltage wave.

Note: this is *NOT* the condition for a "conjugate match" i.e. maximum power transfer does not result in a null voltage refelection coefficient in the
general case.

As a "thought experiment" to support my contention that

rho = (Z - Zo)/(Z + Zo)

Is "natural", consider the case of an infinitely long transmission line of surge
impedance [characteristic impedance] Zo, where in general Zo may be complex e.g.

Zo = sqrt((R + pL)/(G + pC))

Where, R, L, G and C are the primary parameters of the line.

Consider that you are standing in the "center" of this infinitely long line and that you
cut the line with a pair of pliers. Looking in one direction down the line you see a
driving point impedance equal to the surge impedance of that semi-infinite line which
is Zo. Looking in the other direction you will also see a driving point impedance
equal to the surge impedance Zo of a semi-infinite line. And so...

at the center cut you have made, one has an "image match". i.e. at the center cut
you have two equal driving point impedances Zo in each direction facing each other.

This is a Zo match, or "image match", it is not a conjugate match!

Next solder the cut back together and then consider a "wave" launched from one end
of this infinite line in one direction. Such a wave will move in one direction only on down
that Zo line forever and will never be reflected.

Now as the wave is passing the "cut" insert a reflectometer with internal reference
impedance equal to Zo the characteristic surge impedance of the line. This reflectometer
will read a rho of:

rho = (Z - Zo)/(Z + Zo) where Z = Zo and rho = 0, it should of course indicate zero reflected voltage since there are no reflections on this line.

And so I maintain that "Mother Nature" favors the *definition*

rho = (Z - Zo)/(Z + Zo)

or as I like to write it rho = (Z - R)/(Z + R) where I like to use R representing the
Reference impedance i.e. R = Zo because R is the reference impedance inside the reflectometer and may or may not be equal to a Zo as appropriate for the use.

And I have no problem whatsoever with this definition of rho not being null when there is a conjugate match. In the general case for "Mother Nature's" reflection coefficient rho will not be zero when there is maximum power transfer.
In fact there may well be considerable reflected VAR's in that case... VAR's
being Volt Amperes Reactive, i.e. reactive power at the conjugate match point.

On the other hand, I have no argument with those who choose to define rho as:

rho = (Z - conj(Zo))/(Z + conj(Zo)) as long as they are consistent in it's use
and the conclusions they draw from it. Here they will get a null rho for a conjugate
match, and they will not get a null rho for an image match.

But I maintain that is "unatural" and "Mother Nature" naturally likes the classical

rho = (Z - Zo)/(Z + Zo)

Thoughts, comments?

4143. Mother Nature's reflection coefficient...

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 00:28:10 UTC
From: "Peter O. Brackett" <ab4bc@ix.netcom.com>
Message-ID: <uQx2b.12664$8i2.19@newsread2.news.atl.earthlink.net>
Source record: 109787

I believe that "Mother Nature's" voltage reflection coefficient is the well known classical one, i.e.

rho = (Z - Zo)/(Z + Zo) is "Mother Nature's" reflection coefficient.

I believe this simply because it corresponds to the "image match"!

i.e. rho will be null when Z = Zo [NOT conj(Zo)], and is the condition for there to be no reflected voltage wave.

Note: this is *NOT* the condition for a "conjugate match" i.e. maximum power transfer does not result in a null voltage refelection coefficient in the case of a general complex surge impedance Zo.

As a "thought experiment" to support my contention that

rho = (Z - Zo)/(Z + Zo)

Is "natural", consider the case of an infinitely long transmission line of surge
impedance [characteristic impedance] Zo, where in general Zo may be complex and not necessarily a real constant e.g. [Zo is not 50 Ohms resistive or some other
such simple case.] i.e.

Zo = Zo(p) = sqrt((R + pL)/(G + pC))

Where, R, L, G and C are the primary parameters of the line and p is the complex
frequency p = s + jw and the value of Zo is complex in general and may vary with frequency p.

In this thought experiment consider that you are standing in the "center" of this
infinitely long line of surge impedance Zo and that you cut said line with a pair of
pliers.

Looking in one direction down the semi-infinite line you see a
driving point impedance equal to the surge impedance Zo of that semi-infinite
line. Looking in the other direction you will also see a driving point impedance equal to the surge impedance Zo of a semi-infinite line.

And so...

at the cut you have made, there is an "image match". i.e. at the
cut two equal driving point impedances Zo are facing each

other.

This is a Zo match, or "image match", it is not a conjugate match! In a conjugate match Zo would be facing conj(Zo).

Now solder the cut back together and then consider a "wave" launched from one end of this infinite line in one direction. If you have trouble picturing this
situation just imagine it is Douglas Adams sitting on the patio of the Restaurant
at the End of the Universe with his handy wave generator who launches the wave!

Such a wave will move in one direction only on down that Zo line forever and will never be reflected because there are no discontinuities over that infinite
distance.

Now as the wave is passing the "cut" that you made in the center of that infinite
line, quickly insert a reflectometer with internal reference impedance R = Zo,
the characteristic surge impedance of the line.

This reflectometer will read a rho of:

rho = (Z - Zo)/(Z + Zo)

Where, since one sees Zo in both directions at the cut and so Z = Zo and rho = 0, as it should of course indicate zero reflected voltage since there are no
"reflections" on this infinite line with a wave travelling in only one direction.

This is a very natural situation...

And so I maintain that "Mother Nature" favors the *definition*

rho = (Z - Zo)/(Z + Zo)

or as I like to write it rho = (Z - R)/(Z + R) since I like to use R representing the
[R]eference impedance i.e. R = Zo because R is the [R]eference impedance used
inside the reflectometer and whichmay or may not be equal to Zo as appropriate for the
intended use.

I have no problem whatsoever with this definition of rho not being null when there is a conjugate match.

In the general case for "Mother Nature's" reflection coefficient rho will not be
zero when there is maximum power transfer.

In fact there may well be considerable reflected VAR's in that case...
VAR's being Volt Amperes Reactive, i.e. reactive power reflected at the
conjugate match point.

On the other hand, I have no argument with those who choose to define rho
as:

rho = (Z - conj(Zo))/(Z + conj(Zo))

just as long as they are consistent in it's use and the conclusions they
draw from
it. Here they will get a null rho for a conjugate match, and they will not
get a null
rho for an image match.

I can see situations in which such a defintion of rho using conj(Zo) might
be useful,
not necessary mind you, but perhaps more convenient for solving some
problems.

But I still maintain that defining rho in terms of the conjugate of Zo is
"unatural" and
that "Mother Nature" naturally likes the classical...

rho = (Z - Zo)/(Z + Zo)

because that is what she uses herself when she supports the natural
propagation of waves
on transmission lines.

I don't think there's anything to argue about. From _Optics_, by Hecht:
"We define the reflectance R to be the ratio of the reflected power to
the incident power." "When we talk about the 'amount' of light illuminating
a surface, we are referring to something called the irradiance, denoted by
I - the average energy per unit area per unit time." Light and RF are both
EM waves. These scientific facts concerning light have only been known to
physics for about 300 years.

As I read your reply, I am having some difficulty understanding how it
applies to the question.

Are you saying that there can be power when the voltage or current
is always 0? And that this is the error in the sequence of steps
which makes Assertion A false?

Consider again, Assertion A, in more detail this time:
1) Consider a shorted ideal transmission line excited by a single
frequency sinusoidal signal which has reached steady state
2) At quarter wave points along this line, voltages and currents
which are always 0 can be observed -- the standing wave
3) Power is the rate at which energy flows
4) The power (rate of energy flowing) at time t can be computed
using p(t) = v(t) * i(t)
5) Substituting a voltage or current which is always 0 into the
expression above will result in a power which is also always 0
6) From 2) and 5), the power (rate of energy flowing) at quarter
wave points will be 0
7) From 6), the energy crossing quarter wave points is 0
8) From 7), energy can not be flowing down and up the line
crossing quarter wave points

Assume for the moment that all this optical talk has convinced me
that conclusion 8) from Assertion A is false. For Assertion A
to be false, one of the steps in Assertion A must be false.
All the steps in Assertion A seem correct to me.
Can you help me find the false step which makes Assertion A false?

...Keith

I agree with you, Peter. That's what I have been calling the physical
reflection coefficient. At the junction of two transmission lines of
different characteristic impedances, it becomes s11=(Z02-Z01)/(Z02+Z01)
and is usually not equal to rho=Sqrt(Pref/Pfwd).

Dear Roy,

To reduce the amount of bafflegab to an absolute minimum why don't you just say that immediately the value of the reflection coefficient is squared (to allow 'power' to be introduced) half of the information it contains is tossed into the nearest garbage heap.

Any conclusions drawn from following calculations are inevitably ambiguous and highly suspicious to say the least.

To mention one well-known example, that's why it is impossible to deduce the value of the line-terminating impedance from the calculated SWR.

Ignorance is the root cause of these silly, time-wasting arguments.

Get back to basics, erase Smith Charts, mis-quoted worshipped idols, and ill-conceived inventions from your minds and start afresh from R, L, C, G, F and little t.

Fortunately, the success of proposed missions to Mars does not depend on the deliberations of this newsgroup.

Cec, by the way, are there any vinyards in Texas? It *is* as big as France.

Yours, Reg, G4FGQ

Nope, they're not Reg. For Z0-matched systems (which most ham systems are),
rho^2 is all you need to know along with the forward and reflected powers
to completely solve the voltage, current, and phase conditions at the
impedance discontinuity. If you know that Pref1=0, which it does for a
Z0-matched system, half the information is all you need. Given the length
of the feedline, you can calculate the exact load.

> Cec, by the way, are there any vinyards in Texas? It *is* as big as France.

We do have vineyards here and there's a winery about 35 miles from my house.
But I have never gotten up the nerve to go wine tasting there. :-) I tend
to like cold weather grapes.

There can and does exist component energy when the NET power is zero.
You will understand this when you understand complete destructive
interference in light waves represented by the equation

I1 + I2 -2*Sqrt(I1*I2) equation 9.16, page 388, in the 4th edition
of _Optics_, by Hecht.

Two waves are flowing with unchanging energies and producing an absolutely
black ring, i.e. zero irradiance equals zero power.

> Consider again, Assertion A, in more detail this time:

It won't do a bit of good to rehash this until you understand complete
destructive interference. The two interfering waves flow unabated.
You are being fooled by superposition of two waves whose component
energies are completely independent of each other.

> All the steps in Assertion A seem correct to me.
> Can you help me find the false step which makes Assertion A false?

Yes, I already did that more than once. You will not understand until
you understand how two light beams can cause zero power without even
knowing the other wave is there. There is absolutely no change in
the energy levels in the individual waves during complete destructive
interference.

First of all, you're speaking of a circuit with a source impedance R and load impedance Z, rather than a terminated transmission line. Forward and reflected wave terminology is widely used in S parameter analysis, which also uses this model, so I'll be glad to follow along to see if and how S parameter terminology differs from the transmission line terminology we've been discussing so far. Please correct me where my assumptions diverge from yours.

Your "classical definition" of b isn't one familiar to me. v + Ri would of course be the source voltage (which I'll call Vs). So v - Ri is Vs - 2*Ri. Where does this come from and what does it mean?

From your equation, and given source voltage Vs, i = Vs/(R+Z). Therefore, your "classical definition" of reflected voltage b is, in terms of Vs, Vs*((Z-R)/(Z+R)).
>
> and the incident voltage a would be the Thevinins equivalent voltage across
> the sum of Z and R, i.e.
>
> a = (Z + R)i

Since i = Vs(Z+R), you're saying that a = the source voltage Vs (from your two equations). So what you're calling the "incident voltage" is simply the source voltage Vs.

Let's do a consistency check. The voltage at the load should be a + b = Vs + Vs*((Z-R)/(Z+R)) = Vs*2Z/(Z+R). Inspection of the circuit as I

understand it shows that the voltage at the load should be half this value. So, we already diverge. Which is true:

1. I've goofed up my algebra (a definite possibility)
2. I've misinterpreted your circuit, or
3. The voltage at the load is not equal to the sum of the forward and reflected voltages a and b, as you use the terms "forward voltage" and "reflected voltage". If v isn't equal to a + b, then what is the relationship between v, a, and b, and what are the physical meanings of the forward and reflected voltages?

I'd like to continue with the remainder of the analysis, but can't proceed until this problem is cleared up.

Actually, all you've got to do to understand this is to realize that energy is the time integral of power. (Remember that "useless" quantity of power as a time function?) When you integrate power to get energy, you get a constant. That constant is the energy present when power = 0, and it has to be evaluated by knowing something other than just the power. In a transmission line, that energy is stored in the electric and/or magnetic fields during the times energy isn't moving (i.e., when p(t) = 0). Really, math is cool.

Please post this derivation again.

When they say "ideal line" do they mean purely real?

> and that reference you give is not for a load on a transmission line, it is
> talking about a generator supplying power to a load... a completely
> different animal.

Not at all really. The impedance seen by the load can be from
either a source or a source hooked up with a transmission line. It
doesn't matter with this equation.

As Reg points out about the normal equation:

"Dear Dr Slick, it's very easy.

Take a real, long telephone line with Zo = 300 - j250 ohms at 1000 Hz.

Load it with a real resistor of 10 ohms in series with a real
inductance of
40 millihenrys.

The inductance has a reactance of 250 ohms at 1000 Hz.

If you agree with the following formula,

Magnitude of Reflection Coefficient of the load, ZL, relative to line
impedance

= (ZL - Zo) / (ZL + Zo) = 1.865 which exceeds unity,

and has an angle of -59.9 degrees.

The resulting standing waves may also be calculated.

Are you happy now ?"

Reg, G4FGQ

Well, i wasn't happy, because how can you have a R.C. greater than
one into a passive network??? Quite impossible.

But, if you use the conjugate formula, the R.C. will indeed be
less than one.

Convince yourself.

Slick

Keith wrote:
"2) At quarter wave points along this line, voltages and currents which are always 0 can be observed -- the standing wave."

This is proof positive in Keith`s own words that the first 0-volt point encountered by either forward or reflected wave is completely ineffective in halting or abating progress of the waves.

Keith also wrote:
"6) From 2) and 5), the power (rate of energy flow) at quarter wave points will be 0."

The contradiction is obvious. Were energy flow or power reduced by SWR zeros, you would not have multiple zeros along the line.

My pitifully inadequate education could be of no interest to you, Garvin; I'm
just a humble ham. (This is an _amateur_ newsgroup after all.) It is
interesting to me, though, that a person of your age and attainments
would pose as a potty-mouth little black-faced god whenever someone
disagreed with you about something as abstruse as the reflection
coefficient on a transmission line. I can only suppose that your social
education was deficient, or that you really do want your name to be the
most popular in the group's collective killfile. Anyway, you're wasting your
time with the infantile behavior. Most of the fellows on this group are old
men
who gave up that form of discourse when they learned to talk.
By the way, some of your art isn't half bad and shows the influence of some
training. Did you have an art minor in college?

Keith wrote:
"I conclude from this response that you are unable to detect any flaws in the logic of steps 1 to 8."

They are contradictory. That`s a fatal flaw.

Volts and amps on a transmission line are manifestations of E&H fields guided by the line. These fields are generating the volts and amps seen on the line as the wave travels along its length.

Even a hard short or an open circuit doesn`t annihilate the signal on a line. The short or open only produces a reflection.

At the open or short, amps or volts are forced to zero. That event forces the energy which had resided in the H-field or E-field to temporarily be accomodated in the field which is its partner in transporting energy. This doubles volts right at the open or doubles amps right at the short.. This single field is only temporary because in a very short travel distance, energy is again balanced between the two fields.

Note that the open or short does not stop energy flow. It just turns it around as a reflection. This happens at an actual discontinuity. At an SWR interference point, nothing upsets energy flow at all in a uniform line. SWR nulls are just demonstrations of commingled waves passing through each other without serious consequence. For the nth time, were you to separate the going and coming signals, you would find no variation in average signal power in either direction along the line at any point, including the SWR nulls..

Source record: 109806

The short answer is that there isn't any value you can plug in to get accurate results.

According to Reference Data for Radio Engineers, the conductivity of granite is 1E-9 - 1E-11 Siemens/m. That is, it's a good insulator. I wouldn't trust EZNEC's ground models for values that extreme. Furthermore, any field that enters it will eventually be affected by the first conductive soil it encounters underneath, since the granite won't appreciably attenuate the field. EZNEC doesn't have any way of dealing with stratified grounds. The best you can probably do is use a free space analysis.

You conclude wrong. I have already pointed out the flaws in your logic.
Complete destructive interference (power equal zero) does not affect
the energy flow at all in the interfering waves. The forward wave and
reflected wave each have an energy flow that does not affect the other.
That's the flaw in your logic and this is about the 5th time I have
explained it to you. You are being fooled by NET power when you should
be considering component energies. There exists a forward power flow
vector and a reflected power flow vector as explained by Ramo & Whinnery,
a reference I provided earlier.

> 6) From 2) and 5), the power (rate of energy flowing) at quarter
> wave points will be 0

The NET power will be zero. The forward power flow vector is NOT
zero and the reflected power flow vector is NOT zero. The NET power
of zero is complete destructive interference in action. It happens
all the time to two light beams whose energies are not affected by
the interference.

> 7) From 6), the energy crossing quarter wave points is 0

The NET energy crossing quarter wave points is 0. The two component
energies crossing quarter wave points are not 0. They are the
constant forward power flow vector and the constant reflected
power flow vector as explained in Ramo & Whinnery. Their ratio
is the power reflection coefficient. Equation 3, page 350, _Fields_
and_Waves_in_Communications_Electronics_, Ramo, Whinnery, & Van Duzer.

(Pz-)/(Pz+)=|rho|^2

> All the steps in Assertion A seem correct to me.

Yes, that is your problem. They are not correct for the two
component energies.

> Can you help me find the false step which makes Assertion A false?

Here it is again, for the Nth time. There are two waves flowing in opposite
directions, each possessing its own constant energy, each flowing unopposed
end to end in the transmission line.

>impedance discontinuity.

There in one sentence is the whole problem with the "power" approach.
For a complete solution including phase conditions, you have to assume a
Z0-match, and even Cecil acknowledges that is only true for "most ham
systems".

As Reg says, this is because the power approach throws away the phase
information at the start, and if you want it back again, you have to
make assumptions.

So the problem is not that the "power" approach cannot give a complete
solution, but that it cannot do it for all cases. In other words, it
isn't completely general - and that flaw is fatal.

The conventional approach based on voltage (or current) waves doesn't
discard the phase information, but uses it to give a complete solution
for every case. It is completely general, and that's precisely why
engineers use it.

> of course be the source voltage (which I'll call Vs). So v - Ri is Vs -
> 2*Ri. Where does this come from and what does it mean?
[snip]

Yes it should be familiar to you because it is the most common definition
and one you seem to agree with. I presume that you are not used to seeing
the use
of the symbols "a" and "b" for those quantities. The use of "a" and "b" is
widely
used in Scattering Formalism and is less confusing to many than using
subscripts.
In your terminology above the "Vs" symbol is nothing more than the incident
voltage
usually given the symbol "a" in the Scattering Formalism, or the symbol V
with a "+"
sign subscript in many developments. Often you will find authors use a V
with a plus
sign "+" as a subscript to indicate the "a" voltage and a V with a minus
sign "-" subscript
to idicate the "b" voltage. Personally I find the use of math symbols "-"
and "+" or other
subscripts to variables to be confusing, I much prefer the use of "a" and
"b" for forward
or incident and reflected voltages.

Simply put, if a generator with "open circuit" voltage "a" and "internal
impedance" R
is driving a load Z [Z could be a transmission line driving point impedance,
for instance
Z would be the characteristic or surge impedance Zo of a transmission line
if

the generator was driving a semi-infinite line.] then v is the voltage drop
across Z
and I is the current through Z, and so...

a = v + Ri = Zi - Ri = (Z - R)i

is simply the [usual] forward voltage or incident voltage applied by the
generator to the
to the load Z, which may be a lumped element load or if you prefer to talk
about transmission
lines, Z can be just the driving point impedance of a transmsision line,
whatever you wish.

Then its'just a simple application of Ohms Law tosee that b = v - Ri = Zi -
Ri = (Z - R)i is
the [usual] reflected voltage. b is just the difference between the voltage
across Z which is
calculated as Zi and the voltage that would be across Z if Z was actually
equal to R. i.e. the
reflected voltage b is just the voltage that would exist across Z if there
was an "image match"
between Z and R. [If Z is the Zo of a semi-infinite transmsision line you
could call this a Zo match].

Taking the ratio of "b" to "a" just yeilds the [usual] reflection
coefficient as
b/a = (Z - R)i/(Z + R)i = (Z - R)/(Z + R). A well known result. Simple?

[snip]
> From your equation, and given source voltage Vs, i = Vs/(R+Z).
> Therefore, your "classical definition" of reflected voltage b is, in
> terms of Vs, Vs*((Z-R)/(Z+R)).
> >
> > and the incident voltage a would be the Thevinins equivalent voltage
across
> > the sum of Z and R, i.e.
> >
> > a = (Z + R)i
[snip]

Yep you got it all right!

[snip]
> Since i = Vs(Z+R), you're saying that a = the source voltage Vs (from
> your two equations). So what you're calling the "incident voltage" is
> simply the source voltage Vs.
[snip]

Yes, mathematically "a" = "Vs", what else would it be? Nothing mysterious
about
that. The incident voltage is always simply the open circuit voltage of the
source. In
words a is not the source voltage because the source is a Thevinin

equivalent made up
of the ideal voltage generator Vs = a behind the "internal" source impedance
R. A better
way to describe Vs = a in words would be the incident voltage a is the "open
circuit source
voltage".

[snip]
> Let's do a consistency check. The voltage at the load should be a + b =
> Vs + Vs*((Z-R)/(Z+R)) = Vs*2Z/(Z+R). Inspection of the circuit as I
> understand it shows that the voltage at the load should be half this
> value. So, we already diverge. Which is true:
[snip]

No, the voltage at the load is not (a + b) rather it is [the quite obvious
by Ohms Law] v = Zi.

and the sum of the incident and reflected voltage is simply

a + b = (v + Ri) + (v - Ri) = 2v = 2Zi

Now if there is an "image match" and the "unknown" Z is actually equal to R,
i.e. let Z = R
in all of the above, then...

a = Vs

b = 0

a + b = 2Ri

and i = Vs/2R = a/2R.

[snip]
> 1. I've goofed up my algebra (a definite possibility)
[snip]

Only a little :-)

[snip]
> 2. I've misinterpreted your circuit, or
[snip]

No you have it correct!

[snip]
> 3. The voltage at the load is not equal to the sum of the forward and

> "reflected voltage". If v isn't equal to a + b, then what is the
> relationship between v, a, and b, and what are the physical meanings of
> the forward and reflected voltages?
[snip]

I showed those relationships above. There is nothing new here... these are
the [most] widely accepted definitions of incident and reflected voltages.

[snip]
> I'd like to continue with the remainder of the analysis, but can't

> Note that the open or short does not stop energy flow.

I'll accept that, but no energy flows past the short or open where the
voltage or current is zero which is consistent with p(t) = v(t) * i(t).

Similarly, I suggest that no energy flows past the other points in
the line where the voltage or current is zero, again to be consistent
with p(t) = v(t) * i(t).

> It just turns it around as a reflection.

I do understand the derivation from this separation of the going and
coming signals. But I am unable to rationalize this explanation with

the very basic and widely accepted p(t) = v(t) * i(t) and the observed zero voltages and currents.

Do think of that voltage or current 0 at the shorted or open end of the line. In your model, this voltage or current 0 produces a reflection while other voltage or current zeroes do not. Is this consistent?

Consider adding another quarter wave section to the end of the line. The voltage or current 0 remains and to the left of the original end of the line nothing changes, but by your model, suddenly there is no longer a reflection at the original end of the line, but it has moved to the new end. But the voltage and current distributions have remained the same. There is no observable difference. Why are you convinced the reflection point had to move?

> > flaws in the logic of steps 1 to 8. Oh well.
>
> You conclude wrong. I have already pointed out the flaws in your logic.

Actually, not. You continue to resist pointing out which step is wrong.

Is it step 1)?
"1) Consider a shorted ideal transmission line excited by a single
frequency sinusoidal signal which has reached steady state"

Hard for this step to be wrong since it just sets up the
conditions for the experiment.

Is it step 2)?
"2) At quarter wave points along this line, voltages and currents
which are always 0 can be observed -- the standing wave"

This seems to be generally accepted.

Is it step 3)?
"3) Power is the rate at which energy flows"

This is the definition of power.

Is it step 4)?
"4) The power (rate of energy flowing) at time t can be computed
using p(t) = v(t) * i(t)"

This is the well know expression of power in terms of volts and
amps.

Is it step 5)?
5) Substituting a voltage or current which is always 0 into the
expression above will result in a power which is also always 0

Just normal subsitution of actual values into an equation.

Is it step 6)?
"6) From 2) and 5), the power (rate of energy flowing) at quarter
wave points will be 0"

The result obtained after substitution.

Is it step 7)?
"7) From 6), the energy crossing quarter wave points is 0"

If steps 1) to 6) are not in error, then step 7) follows.

Is it step 8)?
"8) From 7), energy can not be flowing down and up the line
crossing quarter wave points"

Simply follows from 7).

You have not yet pointed to any error in the derivation.

If your extensive study of optics leads you to believe that
the conclusion is incorrect, and, if the conclusion is incorrect,
there must be an error in the derivation. What is it?

No amount of repeating "why optics disagrees with the conclusion"
will locate the error in the derivation.

But the derivation is quite simple. If after some reasonable
study you are unable to locate an error in it, it would seem
reasonable to re-assess whether the conclusion is, in fact,
in error.

Since you have not yet pointed to an error in the derivation
(which would be the obvious way to close the question), I
conclude that you have been unable to locate such an error.
Seems reasonable, does it not?

The alternative, that you have located an error but refuse
to disclose it, seems much less likely.

Thanks, it's becoming clear why we're getting different results.

When analyzing a transmission line, the forward and reflected voltages have a meaning that comes from the solutions to the wave equations. One of the fundamental properties of these waves is that their sum is the total voltage in the transmission line. (Likewise for current.) We assume that these are the only voltage waves on the line, so their sum is necessarily the total voltage. We sum these waves, for example, and look at the resulting maxima and minima to get the standing wave ratio. So it was a basic tenet of my analysis that the sum of the forward and reverse voltage waves at any point on the line (including the end) equals the voltage at that point. (Again, likewise for current, with attention paid to the defined direction of positive flow.) This was explicitly given as equation 5 (for voltage) and 6 (for current) of my analysis.

Another property of the waves is that the ratio of V to I of either of the waves equals the Z0 of the cable (equations 1 and 2).

Again making sure I see your model circuit correctly, it's a voltage source of voltage a or V+, connected to R in series with Z. If that's correct, then i = a / (Z + R), so your calculated value of b in your analysis below, (Z - R)i, then equals a * (Z - R) / (Z + R). The sum of a and b is a * (1 + (Z - R) / (Z + R)) = 2 * Z * a / (Z + R).

While in or at the ends of a transmission line the voltage always equals the sum of the forward and reflected voltages, the sum of a and b, which you call forward and reflected voltages, don't sum to the voltage at the load. The voltage at the load is, from inspection of the circuit, a * Z / (Z + R); the sum of a and b is twice that value.

Of course, if we define "forward voltage" and "reflected voltage" to be something other than the waves we're familiar with on a transmission line, while maintaining a definition of voltage reflection coefficient as being the ratio of forward to reverse voltage, we can come up with any number of formulas for reflection coefficient.

And this seems to be done. I have only two texts which deal with S parameters in any depth. One, _Microwave Transistor Amplifiers: Analysis and Design_ By Guillermo Gonzalez, consistently uses forward and reverse voltage to mean exactly what they do in transmission line analysis. Consequently, he consistently ends up with the same equation for voltage reflection coefficient I've been using, and states several places that the reflection is zero when the line or port is terminated in its characteristic or source impedance (not conjugate). And this all without an assumption that Z0 or source Z is purely real. The other book,

however, _Microwave Circuit Design Using Linear and Nonlinear Techniques_ by Vendelin, Pavio, and Rohde, uses a different definition of V+, V- than either of us does, and different a and b than you do. To them, a = V+ * sqrt(Re(Zg)) / Zg* where Zg is the source impedance, and b = V- * sqrt(Re(Zg))/Zg. They end up with three different reflection coefficients, Gammav, Gammai, and one they just give as Gamma. Gammav is V-/V+, Gammai is I-/I+, and plain old Gamma, which they say is equal to b/a, turns out to be equal to Gammai. Incidentally, their equation for Gammav, the voltage reflection coefficient, is:

Gammav = [Zg(Z - Zg*)]/[Zg*(Z + Zg)]

Which is different from yours, Slick's, and mine.

The whole trick seems to be in defining what forward and reflected or reverse voltage mean. In transmission line analysis, the meaning is, I hope, pretty universal and agreed upon. If not, a whole bunch of equations, statements, assumptions, and definitions have to go out the window, along with the idea that those are the only voltages on the line. If you use those widely accepted meanings, you unavoidably end up with the common equation I've been giving for voltage reflection coefficient. (At least nobody reputable so far seems to want to define voltage reflection coefficient as anything but the ratio of reflected to forward voltage, thankfully.) On the other hand, you and the authors of at least one book put a different meaning of forward and reflected voltage (and you two use different meanings), and therefore come up with correspondingly different formulas for reflection coefficient.

At this point I have to concede that in some S parameter analysis at least, various different meanings are given to "forward" or "incident", and "reverse" or "reflected" voltage than are used in transmission line analysis. And the two books I have disagree with each other, and both disagree with you, as to what they do mean. With that kind of non-standardization, it's useless to argue which is "more right" than another. It just points out the importance of carefully defining what you mean by forward and reverse voltages before you begin your analysis -- and being very careful about what conclusions you draw from the "reflections" or lack of them. When the definitions are different from those used with transmission lines, the meaning and consequences of reflections and impedance match are correspondingly different.

Your analysis is self consistent, given your definitions of forward and reverse voltage. So are the analyses in the two books I have dealing with S parameters. So all three of you reach different but valid conclusions. Unless someone comes up with a convincing argument that one definition of forward and reverse voltages is better or more meaningful than another in that context, I have to agree that any of these three, or any of an infinite number of other possibilities, is equally valid for S parameter analysis.

But not for transmission lines. There, forward and reverse voltages do have real meaning and a rigorous derivation. So anyone redefining them

in that context is certainly deviating from very well understood usage.

Consequently, I don't see how it would be productive, or add insight to the problem of voltages, currents, and reflections in a transmission line, to bring in S parameter terminology which obviously differs and in an inconsistent way from author to author. I'll be glad to continue discussing transmission lines, which is what this discussion originally involved, with the first step being for someone disagreeing with the formula for voltage reflection coefficient to point out which of the equations or assumptions preceding it are incorrect. Your analysis disagrees with equations 5 and 6 and, I believe, 1 and 2, by virtue of your different definition of forward and reverse voltage. I don't believe this can be justified within and at the end of a transmission line -- if the forward and reverse voltages on the line don't add up to the total, then you have to come up with at least one more voltage wave you assume is traveling along the line (which summed with the others does equal the total), and justify its existence.

Your analysis overlooks that we are discussing an ideal line that has reached steady state. Before the line reaches steady state, energy does cross the quarter wave points, but, of course, while this is happening the voltages and currents at the quarter wave points are not yet zero.

As an aside, were we to discuss a line that was not open or shorted but rather terminated in other than its characteristic impedance, we would still find voltage and current minimas. At these minima, rather than the energy flow being 0 as it is for a shorted or open line, the energy flow (power) is exactly the energy being delivered down the line.

Something similar occurs while an opern or shorted line is approaching steady state.

Keith wrote:
"Why are you convinced the reflection point had to move?"

This is the case when a line is extended to greater length, and the short or open also is moved to the new end of the line.

Ever had a short or open somewhere in the middle of a line? I have, and can testify that the signal doesn`t get past a real hard short or open in the line. As energy can`t be destroyed it had to be reflected by the hard short or open.

In the case where the line short is moved to a point nearer the source, or where the short or open is moved to a place more distant on the line from the source, we know the energy travels all the way to the actual short or open where it is reflected because nulls occur at several points along a long transmission line. If the energy were turned around before it reached the end of the line, nulls more distant from the source than the turnaround point would not exist. There would be no energy at the actual short or open at the end of the line were the energy turned around before it reached the end of the line.

Thanks for following along with my development. I like to develop stuff from first principles, instead of quoting often questionable sources.

Roy apart from a few typos and a small factor of 1/2 it seems that we agree on everything!

Sorry if I messed up a little with typos, and... there is that potentially confusing but unimportant factor of 1/2 that appears in my definitions of the incident "waves" a and b.

Your claim as to my definitions being quite different from the "mainstream" of transmission line theory was a bit hasty, because in fact with a closer look I believe that you will see that my definitions and yours [Which are hhe mainstream transmission line definitions and equations] only differ by a simple numerical factor of 2. I don't use that factor of 1/2 because it drops out whenever you take a ratio of waves anyway.

Perhaps I should have defined my a to be a = 1/2(v + Ri) and b = 1/2(v - Ri) instead of a = v + Ri and b = v - Ri as I have done. Including that factor of 1/2 in my a and b makes them identical to your incident and reflected voltages.

This factor of 1/2 is a very minor "scaling" difference in the "waves" and there is absolutely no difference in reflection coefficient, or indeed in

Scattering Matrix definitions since the factor of 1/2 in each of "my" wave definitions simply cancels out in rho = b/a, when you divide b by a to get rho or indeed in calculating with wave vectors and Scattering Matrixs of any order. My definition of the scaling factor [1/2] for the wave variables works as well as any other as long as consistency is maintained. Like you I have found that different Scattering Theory books often use a variety of different scaling factors in defining the waves, for instance some use a factor of 1/2*sqrt(R) = 1/2*sqrt(Zo) in the definition of the waves, etc... It simply doesn't matter as long as you are consistent.

In any case, the scaling value in the definition of the "waves" was not my point.

The point I was trying to make was to address the subtle point initiated by Slick, i.e. the one about the definition of rho which is the ratio of reflected to incident waves, where the scaling factors drop out, and whether the CONJUGATE of the reference impedance should be used in the definition for rho or not.

My point was that the conventional definition of rho = (Z - R)/(Z + R) without the CONJUGATE is in fact the "natural" definition for wave motion whether on transmission lines or in impedance matching to a generator. And...

That with the conventional definition of rho in the case of a general Zo the reflected voltage will *NOT* be zero at a conjugate match. At a conjugate match, the classical rho and b will only be null in the special case of the reference impedance Zo being a pure real resistance.

Keith wrote:
"Is it step 7)?"

"7) From 6), the energy crossing quarter wave points is zero"

False, as are several other of Keith`s speculations.

Standing waves throughout a long transmission line with a hard short or open-circuit at its end are proof enough that SWR nulls other than the one at the actual discontinuity don`t bring the energy crossing 1/4-wave points to zero. SWR nulls other than the one at the actual open or short have no effect on traveling waves, absent an additional actual discontinuity. SWR can`t exist without energy flow in both directions. Energy flow is continuous. It doesn`t start and stop at SWR nulls. This continuity is proved by measurements at the nulls, taken in one direction at a time.

No speculation or even math is needed to observe this behavior on an actual line. It is usless to try to conform the observable to some theory. It is far more productive to conform theory to the observable.

Keith wrote:
"At these minima, rather than the energy flow being 0 as it is for an open or shorted line, the energy flow (power) is exactly the energy being delivered down the line."

The power is not zero at an SWR zero, provided that the line has power flow. The power flow at the specified null is equal in forward and reflected wave directions as shown by the complete zero.

Power delivered by the source and to the load is the forward power minus the reflected power. In the case of a complete reflection, the difference between forward and reflected power is zero, so the load is rejecting all the forward power, which is turned around and becomes the reflected power.

In a lossless line, forward and reflected powers flow unabated from end to end of the line and are thus have their same amplitudes wherever they are measured in the line, including SWR null points.

This formula is Gonzalez's definition of voltage
reflection coefficient, based on *power wave*
theory (not *transmission line* theory) on page 48
of his *second edition*. We need to keep in mind
that a power wave is a different kind of wave than
the ones that we are used to thinking about in
transmission lines (Gonzalez's words).

If you don't have his second edition, I suggest
get on-line and buy it. It has a lot of stuff not
found in the first edition. The discussion of
power waves is excellent and readable, with some
mental suffering.

The power wave concept is quite valid. We need to
come to grips with this and learn to accept it. It
is the actual basis for microwave simulation
programs. In these programs transmission lines are
treated as "circuit elements" with certain
properties and calculated scattering parameters.
But we must wear a different "hat" when dealing

with it. The idea of "power wave" requires some
meditation.

I discussed some of this in a previous post.

Another property of rock, granite and like is that they "eat" RF. Experienced that when driving around and operating from areas in OK3 and VE3 (Kingston). Just like ocean gives you 10 -15 dB plus, seems that rocky areas take away about as much. Like driving into an anechoic chamber vs. into amplifier at the ocean beach.
Looks like perhaps absence of good reflecting?
As far as modeling, use it to compare various designs in similar conditions and perhaps try them in real life, see how they reflect the modeling.
I would use radials or ground screens under antennas, perhaps good verticals will perform better than horizontals?

4182. recommendations on non-crank-up self-supporting towers

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 13:19:48 UTC
From: "Carl R. Stevenson" <wk3cqth@wk3c.com>
Message-ID: <U7J2b.2792$EC4.53108@nnrp1.ptd.net>
Source record: 109623

I'm looking for recommendations and rough costing info (from
experienced owners of the make/model they tout) on
non-crank-up (fixed) self-supporting (un-guyed) towers .

(I would *consider* buying an excellent condition used tower
within 100 miles or so radius of Allentown, PA, but I'm thinking
primarily about buying a new tower. I have no ht. restrictions
where I live and want to move on this before winter sets in, so
I need to make a decision and act ASAP.)

I'm looking at the range of 55'-75' ish, depending on several
factors:

1) cost vs. height and wind loading
(looking to put a "large" (6-9 element?) 6m beam just above the
top of the tower, with a 2m/70cm/? satellite array above that, and
a PD-220 "SuperStationmaster" side mounted with the tip near the
top ... and almost certainly some other small VHF/UHF antennas
side-mounted at various locations ... but the latter will not contribute
significantly to wind loading as they will be very modest)

2) code here requires 90 mph wind survival rating

3) I have space for a foundation base up to the 5'x5' range
by, say 6' deep. Actually, I have 12 acres, but where this tower
will go, next to the house between some windows, I want to
limit the size to 5'x5' if at all possible (it's rocky here and digging
that hole will be a SOB ... I'll almost certainly look to have it dug
by someone with a machine ...)

4) a HD rotor must fit inside the top section, with a top plate
for thrust bearing available to handle vertical loads ...

5) Within cost constraints, there is no such thing as "too heavy-duty."

Any help, please?

73,
Carl - wk3c

4183. Determining antenna resonance with a grid dip meter

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 14:00:40 UTC
From: Tom Coates <tecoates@comcast.net>
Message-ID: <rQCdnfXCtI-Y9daiXTWJgA@comcast.com>
Source record: 109627

I recall reading about this many years ago but can't find it in any of the books I have now.

How do I couple the meter to the antenna?

The project is a 3-element 2 meter yagi and I'm trying to set the length of the driven element. I can't find a dip within the band using the rig and an swr bridge.

Tom, N3IJ

Hi all,
the electrical codes differ in different countries. Consult the
current one in your country.

> One is that the Radio Shack tester can detect certain forms of
> mis-wiring, but there's at least one which it cannot detect. This is
> one in which you have a three-wire outlet, hooked up to a two-wire
> power feed (one which doesn't actually have a ground), and the
> installer simply wired the "neutral" and "ground" screws together at
> the outlet.
This setup was legal and widely used in Czechoslovakia for many years.
Now it should not be used in new or reconstructed instalations, but it
is still in use in thousands of houses and flats. It doesn't seem
hazardous provided that the network is fused properly.

> ...
> The other reason I'd discourage wiring the power-outlet ground to your
> hot-water-heater pipe, is that the National Electric Code doesn't
> permit this. If a short circuit occurs somewhere on this circuit, it
> would cause your water pipes to carry some of the current back to the
> house ground, and this could result in a shock hazard for anyone in
> contact with the pipes (e.g. somebody in a shower or tub).
The Czech code requires to interconnect all tubing and conductive
items in a bathroom and connect them to the protective wire
(protective AND NEUTRAL in older installations, see higer)...

But Ian, what we have been arguing about for two years is what happens to the energy around a *Z0-match point*. Now you admit that, for a Z0-matched system (which most ham systems are) the power approach yields a "complete solution including phase conditions". We are making progress.

> As Reg says, this is because the power approach throws away the phase
> information at the start, and if you want it back again, you have to
> make assumptions.

For an energy analysis, you don't need the phase information. Energy, like SWR, is the same for 50+j50 and 50-j50.

> So the problem is not that the "power" approach cannot give a complete
> solution, but that it cannot do it for all cases. In other words, it
> isn't completely general - and that flaw is fatal.

You don't understand the purpose of a "power" approach. It is not to solve for the phases. It is to analyze the energy flow. For that purpose, like SWR, it is not necessary to know the sign of the reactance. I have specifically said that the power approach does not attempt to replace conventional approaches. It augments conventional approaches to determine the details of the energy flow, something the conventional approach sadly lacks.

The length of the driving element is not critical and may not resonate by
itsself depending on the matching device used.

No violation at all, Richard. The power (irradiance) that is lost
in the black rings is gained in the bright rings as explained in
Optics, by Hecht where he says constructive interference is
always equal to destructive interference.

The reluctance seems to be your unwillingness to read the replies
which point out exactly that.

> I'll accept that, but no energy flows past the short or open where the
> voltage or current is zero which is consistent with p(t) = v(t) * i(t).

No NET energy flows past such a point. Plenty of component energy flows
past the point in both directions as explained in Ramo, Whinnery, & Van
Duzer.

> I do understand the derivation from this separation of the going and
> coming signals. But I am unable to rationalize this explanation with
> the very basic and widely accepted p(t) = v(t) * i(t) and the observed
> zero voltages and currents.

You are talking about NET energy and NET power. Drop down one level to
component energy and power and all will become clear - especially if
you take a look at light wave interference patterns.

> Do think of that voltage or current 0 at the shorted or open end of the
> line. In your model, this voltage or current 0 produces a reflection
> while other voltage or current zeroes do not. Is this consistent?

Yes, perfectly consistent. The short or open end of the line is a physical
impedance discontinuity. The other voltage and current zeros are NOT
physical impedance discontinuities. They are a result, not a cause of
anything. You are simply confusing cause and effect.

> Consider adding another quarter wave section to the end of the line.
> The voltage or current 0 remains and to the left of the original
> end of the line nothing changes, but by your model, suddenly there
> is no longer a reflection at the original end of the line, but it
> has moved to the new end. But the voltage and current distributions
> have remained the same. There is no observable difference.

Are you telling us that you cannot locate the physical short or open
at the end of the line and don't observe any difference between a physical
short or open and a piece of continuous transmission line? All you have
to do is open your eyes.

4189. What is the best method of mounting a pvc-tube fitted Slim Jim?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 14:59:42 UTC
From: "L. Overdulve" <luco.removethisfirst@chello.nl>
Message-ID: <yBK2b.95735$JX1.18422425@amsnews02.chello.com>
Source record: 109633

Hi everyone!

At last (after some years) I will build a weather protected Slim Jim, fitted into a pvc tube.
I have found the right method of calculating the dimensions and I expect no problems so far.
But...after all is done, the antenna will have to be mounted to the mast (metal). What is the best way of mounting such an antenna? I have searched the web, but I could not find anything.

At this site (http://www.trival-antennas-masts.com/trival-com/Frames.htm) I found this mounting frame, but because it is made of a conducting material perhaps it is not a good idea...
May be the pvc tube can be mouted directly to the mast using two of three giant cable ties, but perhaps this will put the antenna too close to the conducting mast...

Thanks for thinking about this and thanks in advance!

Luc

73s to everyone!
I'm an SWL from Italy.
At last Pordenone's exhibition I've bought the "scanner antenna"
indicated as subject of this thread for about 15 euro.
The antenna was sell without technical information and manual.
The dealer indicated that it cover from 25 to 1300 Mhz, but nothing
else.
Does anyone have other information about it?
Thanks for your attention

>
> This seems to be generally accepted.

This is where your confusion starts. There are points where the
NET voltage and NET current are zero. Those are merely the points
where the forward Poynting vector and reflected Poynting vector
are out of phase.

> Is it step 3)?
> "3) Power is the rate at which energy flows"
>
> This is the definition of power.

So please apply it to the forward Poynting vector and the reflected
Poynting vector as described in Ramo & Whinnery.

> Is it step 4)?
> "4) The power (rate of energy flowing) at time t can be computed
> using p(t) = v(t) * i(t)"

This is NET power. Your sin is not a sin of commission. It is a
sin of omission.

> Is it step 5)?
> 5) Substituting a voltage or current which is always 0 into the
> expression above will result in a power which is also always 0
>
> Just normal subsitution of actual values into an equation.

Again, you are dealing only with NET power when you need to be dealing
with component energies.

> Is it step 6)?
> "6) From 2) and 5), the power (rate of energy flowing) at quarter
> wave points will be 0"

>
> The result obtained after substitution.

Again, your assertions apply ONLY to NET power which is not what
is being discussed.

> Is it step 7)?
> "7) From 6), the energy crossing quarter wave points is 0"
>
> If steps 1) to 6) are not in error, then step 7) follows.

The NET energy is zero. The component energies are not zero.

> Is it step 8)?
> "8) From 7), energy can not be flowing down and up the line
> crossing quarter wave points"
>
> Simply follows from 7).

And completely false for component energies.

> You have not yet pointed to any error in the derivation.

Yes, I have, numerous times. Let me give you an analogy. To prove
my point I say: "My pickup is white. Please prove otherwise." My
statement is absolutely true and absolutely irrelevant. So are
yours.

> If your extensive study of optics leads you to believe that
> the conclusion is incorrect, and, if the conclusion is incorrect,
> there must be an error in the derivation. What is it?

Your error is one of omission. Your assertions are simply not
relevant to the discussion.

> But the derivation is quite simple.

Yes, too simple and completely irrelevant.

> Since you have not yet pointed to an error in the derivation
> (which would be the obvious way to close the question), I
> conclude that you have been unable to locate such an error.
> Seems reasonable, does it not?

Since you have not proven that my pickup is not white, you lose
the argument. See, I can do the same thing you are attempting.

4192. Added a few turns.....

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 15:28:53 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <o6idnRBhS6YI4daiU-KYvA@comcast.com>
Source record: 109635

I was running my dipole with a 6 turn, 2-5/8" dia rg8x coax choke
at the feed point. I got the following "dips" on my SWR meters:

2.330 mhz, 1:1
8.000 mhz 1.8:1
23.615 mhz 1.2:1

A message I got specified that at 6 turns (2.342 uH), I might want
to consider adding a few turns. I added 3, for a new inductance of
4.798 uH. Now I get the following "dips" in my SWR meters:

2.330 mhz, 1:1
8.040 mhz, 1.8:1
13.630 mhz, 1:1 <<<new!
23.615 mhz, 1.2:1

I didn't add any coax to make the turns - I simply used the slack
in the line I had to wind the turns. I can't wind any more without
adding coax at this point..... I have 8-1/2' of rg8x between the
coil and my Z11 autotuner.

Anyone know what's going on here? FYI the antenna is a 153'2"
dipole wrapped closely around a brick building. The feedpoint
is on the third floor window, the ends are 1) chest height and
2) 10' high. Everything is very well grounded (covered here
before)......

Hi Cecil,

So you contradict yourself. Two waves do not produce a black ring,
they produce two rings (one dark, one bright) over an interval of one
wavelength (the proper bounds for an energy solution) and the sum of
them are the same as the applied powers - not zero. Choosing lesser
bounds to craft your "proof" constitutes an invalid proof.

A good reference is HP's application note, AN 95-1, available for download
from Agilent: http://contact.tm.agilent.com/Agilent/tmo/an-95-1/index.html

Another good reference is: _Fields_and_Waves_... by Ramo, Whinnery, and
Van Duzer, section 11.09. The basic equations are pretty simple:

b1 = s11*a1 + s12*a2 b2 = s21*a1 + s22*a2

In fact, power waves are used almost exclusively in the field of optics,
the "other" EM waves. Since the phase of light is extremely hard to
measure, it is deduced from the irradiance (power) patterns. The same
deductive logic can be used with RF transmission lines (if anyone actually
cares about logical thought).

Hi Cecil,

And what makes this remarkable? Your obvious gusting on to no effect
or his lack of understanding?

If what you said comes to no particular change once, twice, or thrice,
why would you think two or more times beyond that will do it? You've
shown no less obduracy to others and your example hardly offers a
compelling resolution to either of your problems.

Usually a couple of loops of coil are fastened to the end of the transmission line and the grid dip coil is inserted into the loops. Seems I had more fun with that old grid dip meter than I now do with an antenna analyzer. It contains a 6C4 and still works.

... his ability to ignore the great body of scientific facts contained
in the field of physics from which I have previously quoted. Most of what
we are discussing has been known for about 300 years. If he (and you) choose
to ignore the known facts of physics, there is absolutely nothing I can do
about it. Understanding interference patterns is centuries old but my daughter
still cannot understand them. Probably only a small percentage of the human
population understand interference patterns - which is a pity.

Hi Keith,

One obvious and glaring mistake that you share with everyone is found
in your step (2).

To observe these variables necessarily involves extracting energy and
consuming power. Hence the Assertion is rendered false in its own
confirmation.

So what now? Step back and retract (2)? Then where's your proof?
Offer that the "assumption" that replaces the reality of this step
renders the reality unnecessary?

These issues are then argument in faith between those who have none.
This is because other methods that do employ reality exist to offer
"proof" in equal measure, and yet no one seems prepared to go there,
or show any awareness of those paths.

You need only recite the virtues of the TR/ATR tube in RADAR systems
to offer Richard, KB5WZI, a model he can accept, and one that is
solidly based in reality. You could posit the complete solution to
the interference model so expounded upon by Cecil, except he seems to

have a patent on its application to his uniquely crafted solutions.

I have an AN/PRM-10 GDO and I will not part with it.

I have a MFJ 259B and I will not part with it, either.

Follow the instructions above with a GDO. For more detailed analysis the
MFJ 259B or equivalent Analyzer will do a FB job.

Hi Ken,

One of several things going on, barring more data.
>I have 8-1/2' of rg8x between the
>coil and my Z11 autotuner.
How much distance between the choke and the feedpoint? How much
distance between the auto tuner and your station?

If considerably less then that means you and your domicile are
immersed in the very near fields of the antenna. This complicates
matters and certainly offers the prospects of Common Mode issues
galore (simply through imbalances offered by life in the 'burbs).

How near is too near? For 160M you cannot escape being part of the
radiator by living in the conventional house in a conventional tract.
Higher frequencies only reduce this prospect by degrees. For 20M the
near field, by various assessments, extends as little as 20M away from
the antenna to more conservative expectations of 100M to 200M.

How much does it matter? You seemed to have reduced what Common Mode
issues you could perceive enough. This doesn't mean you completely
removed them, just reduced them below your thresh hold of detection.
So, in that sense, mattering is an issue of detection and if your
neighbors do not detect your activity, nor do you burn yourself on
equipment ground, then there is no "problem."

If you want to increase your thresh hold of detection, break a ferrite bead in half (to get a C shaped, half torus) and wrap the leads of a high output LED around it once (same thing as shorting the leads and inserting the half torus through them). Red LEDs rated at 1 Candela or better are very suitable and can be found at Radio Shack. Hold the half torus near conductors and check for a glow. This should offer 10 to 100ï¿½A sensitivity and something new to worry about. ;-)

I rember reading a thread awhile back that suggested one could get
an RF burn even at 5 watts, so I tested for that. I transmitted on all
freqs while touching various points (case screws, Pl-259 cases, etc.)
while I ramped up the freq from 1.8-30 mhz continuos <sp>. I felt no RF
and saw no change in SWR or power draw when tapping these points.

4210. Re: A Subtle Detail of Reflection Coefficients (but important to know)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-26 17:16:59 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vkn5g36d7g5cf6@corp.supernews.com>
Source record: 109654

In transmission line analysis, we're not free to rescale the forward and reverse voltage waves, unless we also scale all the voltages, currents and powers accordingly. The forward and reverse waves have to add to the total voltage in the line and at its ends, and the ratio of each component to the corresponding current component has to equal the Z0 of the line. It's quite apparent that in S parameter analysis you're quite free to scale them as you wish, as you have. Vendelin et al didn't just scale them, but chose a set of V+ and V- which aren't even related to a and b by the same constant.

By defining V+ and V- as we wish, we can make the reflection coefficient V-/V+ to be zero when there's a Z0 match, when there's a conjugate match, or when any other impedance of our choice is used as a termination. And when we relieve the requirement that the sum of V+ and V- add to the total voltage, we can have any value of V+ we choose, when V- is zero. The various analyses I've seen have made different choices, and arrived at different V+, V-, and voltage reflection coefficient values.

Again, though, when dealing with a transmission line we don't have the luxury of choosing any definitions of V+ and V- we want. Consequently, in a transmission line, the ratio of V-/V+, universally defined at the voltage reflection coefficient, can be calculated with the familiar non-conjugate formula. The formula can be derived as I did it, from basic principles. And from it or other methods, we can conclude that when a transmission line is terminated in its characteristic impedance, there is no reflection of the voltage (or current) wave. When it's terminated in the complex conjugate of its characteristic impedance, or any other impedance except its characteristic impedance, there is a reflection.

From: rjw01@yahoo.com
Message-ID: <1db36613.0308260934.1460401d@posting.google.com>
Source record: 109656

Want to make a small directional antenna in UHF bands- either a yagi or HB9CV or ??? Want the elements to be less than .5 WL. Anyone know how to center or end load elements so that width of antenna could collapse down to half to two-thirds the normal .5 WL? Perhaps some other antenna design would do it but element loading comes first to mind. Goal is VSWR of 1.5, a FB of 10db or better and beam width of +/- 20 to 30 degress. In the 900 mhz band would like to limit width to say 3 to 4 inches versus the nominal 6+. Any thoughts or directions to look? Thanks!

> . . .

I'll restate something I mentioned before (first incorrectly, then corrected). Connecting a load to a transmission line which is the complex conjugate of the transmission line Z0 does *not* guarantee maximum power delivery from the source, or to the load. The load impedance which provides maximum load power is the complex conjugate of the impedance looking back from the load toward the source. That impedance is the source impedance transformed through the transmission line between source and load, and it's not generally the same as the line's Z0, or its complex conjugate. When this condition of maximum load power is met, there will almost certainly be voltage and current wave reflections on the line -- there would be none only if the optimum load impedance coincidentally happened to be equal to the line Z0. So the argument that there can be no reflection of the voltage wave under the condition of maximum power transfer is wrong.

You didn't show differently in your analysis, and no one has stepped forward with a contrary proof, derivation from known principles, or numerical example that shows otherwise.

He certainly wasn't including Max Born and Emil Wolf when he said "We".
They define reflectance in terms of indices of refraction i.e.
(n1-n2)/(n1+n2).

Hi Peter,

The scenario begins:

"A 50-Ohm line is terminated with a load of 200+j0 ohms.
The normal attenuation of the line is 2.00 decibels.
What is the loss of the line?"

Having stated no more, the implication is that the source is matched
to the line (source Z = 50+j0 Ohms). This is a half step towards the
full blown implementation such that those who are comfortable to this
point (and is in fact common experience) will observe their answer and
this answer are:

"A = 1.27 + 2.00 = 3.27dB"

"This is the dissipation or heat loss...."

we then proceed:

"...the generator impedance is 100+0j ohms, and the line is 5.35
wavelengths long."

I could have simply given you the answer to allow you to fulfill your
challenge above (by predicting the generator Z from that answer), but
I thought a simple resolution of a real value would be more to the
point - quicker that is.

I know you eschew academic references in favor of "first principles,"
but others may want more material than the simple puzzle aspect.
They can consult "Transmission Lines & Networks," Walter C. Johnson,
Chapter 13, "Insertion Loss and Reflection Factors." But lest those
who go there for the answer, I will state it is from another
reference, Johnson simply is offered as yet another reference to
balance the commonly unstated inference of SWR mechanics being
conducted with a Z matched source. "Transmission Lines," Robert
Chipman is another (and not the source of the puzzle either).

The scaling is defined by the s-parameter specification. Nobody is
free "to scale them as you wish". For instance, a1 is defined as:

(V1+I1*Z0)/2*Sqrt(Z0)

The Reflectance is equal to the square of the amplitude reflection
coefficient.

R = Ir/Ii = [(n1-n2)/(n1+n2)]^2

Hecht says the definition "leads to" the last term above.

Message-ID: <big90p$c1h$1@titan.btinternet.com>
Source record: 109662

Andrew, Just enter in EZNEC :

Conductivity = 0.1 milli-Siemens,

(Or Resistivity = 10,000 ohm-metres.)

Permittivity, or dielectric constant K = 4,

and you will get results just as accurate as EZNEC is able
to provide with more usual values of ground 'constants'.

At HF, in the case of granite, as discussed below, the
controlling factor is permittivity K and any reasonable
very high value for resistivity will suffice. Granite is a
fairly low-loss material. Roy, you should have more
confidence in your 'baby'.

Soil, or whatever you are blessed with, has an
impedance Zs = Rs - jXs. It can be modelled to the
first order of accuracy by a resistance in parallel
with a capacitance.

Rs and jXs are the equivalent series components.

Soil resistivity is that measured between opposite
faces of a 1-metre cube of the material. Easy to
visualise and understand.

Capacitance is that measured between a pair of
1-metre square plates spaced 1-metre apart,
multiplied by the permittivity of the material.

Unless iron filings or crushed ferrite are mingled with the soil, the
permeabilty of this 1-metre cube of space will be unity and can be ignored.
Such mixtures are not known in the natural world.

Soil loss occurs due to current flowing in the soil
through Rs. Note carefully that Rs, a series
component, reduces as frequency increases. And
so soil loss decreases with increasing frequency.

Permittivity K increases fast with water content. In
solid rock moisture content is negligible and K is
that of the material itself, crudely 3 to 7. Mica is
a rock, K = 7. Quartz, another rock, K = 4.
Sahara sand has a lot of dry air in it, K = 3.

Lumping all sorts of backyards together, soil impedance is resistive below 1 or 2 MHz with a small -ve angle. Around 5 to 12 MHz impedance has an angle around 45 degrees. At 30 MHz impedance is that of a lossy capacitor, but low in value and therefore a good reflector. At VHF soil impedance is very low, has a high negative angle, and is an efficient low-loss reflector.

The best reflectors are those with a small impedance magnitude relative to 377 ohms combined with an impedance angle approaching -90 degrees. The angle of incidence is also in there somewhere. But don't forget skin depth in the soil is quite shallow at VHF and only the top thin surface layer may be involved.

If anybody intends to do any calculations it's far more convenient and meaningful to work in practical terms of ohm-metres. Milli-Siemens sounds pseudo-scientific and is not particularly impressive.

The capacitance between two 1-metre square plates, spaced 1-metre apart, is 8.8 picofarads. Doesn't seem very much. But with an ordinary garden soil permittivity of 15, the impedance at 7 MHz is - j170 ohms. And with an ordinary garden soil resistivity of 170 ohms-metres we have an angle of -45 degrees.

Two programs, EARTHRES and RADIOETH may be of interest. Download in a few seconds from the following website and run immediately. In addition, program SOILSKIN, as may be expected, calculates skin depth in soil.

Again, Born and Wolf disagree with Hecht. They define Reflectivity as
being the square of the reflection coefficient.

> Hecht says the definition "leads to" the last term above.

Certainly he didn't feel that some relative amounts of power are what
determine the indices of refraction of the system. That would be
ridiculous.

It would seem that if we are allowed to posit, for the purposes
of discussion, the existence of ideal transmission lines, we should
also be allowed to posit the existence of ideal observation tools.

Once the world of the ideal is agreed and understood, then will be
the time to add in the necessary complexity so that the model agrees
with reality to the desired degree of accuracy (one dB, perhaps?).

When the discussion moves too quickly to the complexities of reality,
it seems that a thorough understanding of the basics is often not
attained.

the reference you gave is looking at a generator connected to a load. true,
it doesn't matter if there is a transmission line in between the generator
and the 'load' but the impedance being used is the one transformed back to
the generator end of the line, not the one at the far end of the line... so
basically that equation is not a transmission line equation, it is a
generator to load reflection calculation done to maximize power not to
satisfy kirchoff.

Actually, no.

> I have, and
> can testify that the signal doesn`t get past a real hard short or open
> in the line.
> As energy can`t be destroyed it had to be reflected by the
> hard short or open.

Or just stopped and stored, perhaps. This is certainly what happens
when you excite the line with a step function rather than a sinusoid.
When excited by a sinusoid, no energy moves at the quarter wave points
where the voltage or current is always 0. As you move away from the
quarter wave points, more and more energy moves on each cycle until
a maximum amount of energy is moved at the point half way between the
quarter wave points. And then it decreases back towards the next
quarter wave point.

All of this is easily visualized by observing the amplitude of the
p(t) function at various points along the line.

> In the case where the line short is moved to a point nearer the source,
> or where the short or open is moved to a place more distant on the line
> from the source, we know the energy travels all the way to the actual
> short or open where it is reflected because nulls occur at several
> points along a long transmission line.

"we know" is rather strong. I would strongly suggest that no energy
crosses those points in the line where the voltage and current are
always zero since p(t) is always zero at these points.

> If the energy were turned around
> before it reached the end of the line, nulls more distant from the
> source than the turnaround point would not exist.

Not so, the line has reached steady-state. Now the nulls exist. They
did not exist before the line reached steady-state.

> There would be no
> energy at the actual short or open at the end of the line were the
> energy turned around before it reached the end of the line.

Not necessarily. Only once the line has been charged, does the energy move back and forth between the quarter wave points, while not crossing them.

Try visualizing how a step function charges the line. How the voltage step propagates down the line. How the voltage step is reflected at the open end and starts travelling back towards the start. How between the start of the line and the returning voltage step, energy is flowing to charge the line, but between the returning voltage step and the open end of the line, the energy previously delivered is statically stored in the capacitance of the line. How once the line is completely charged, no current flows, there is no power, and the energy delivered during charging is stored in the capacitance.

Sinusoidal excitation is more difficult to visualize, but the prinicipal is the same.

I do not see any flaw in step 7).

Assuming that step 6)
"6) From 2) and 5), the power (rate of energy flowing) at quarter
wave points will be 0"
is correct, then step 7)
"7) From 6), the energy crossing quarter wave points is 0"
must also be true, since,

If the rate of energy flowing is zero, then there is no energy
flowing so there can not be any energy crossing the point.

I do not find that step 7) is in error.

If there is an error in the final conclusion then I do not think
that it is an error in step 7) which causes the final error,
but, rather, the error must be in one of the earlier steps.

Hi Keith,

All fine and well, but you have simply "defined" your own solution. You haven't explored it, explained it, or learned from it. Saying "it is thus" is meaningless. It's like Cecil's logic of zero power arising from the combination of all possible powers. "A gazzillion watts facing -gazzillion watts is zero watts - how can you deny a gazzillion watts?"

You may allow yourself these ideal tools, but you have wholly neglected their description, method, and application. The same solutions exist in reality, they are simply rough around the edges. Knowing the scope of error in context let's us judge for ourselves how significant the argument is. As I pointed out, there are a number of metaphors available to do this, and they still go wanting.

This so-called "ideal" is an illusion. I've measured physical constants out so many decimal places that the random noise of the big bang limited its accuracy, and yet there were still more places to report if anyone wished hard enough to believed in it. Perfection allows for error too.

> this answer are:
>
> "A = 1.27 + 2.00 = 3.27dB"

Interesting. I'd first have asked if the line was really 50 ohms,
completely nonreactive. If so, L/C=R/G and I'd have said A=3.266dB.
If the line was just 50 ohms nominal, then I can think of at least one
scenario in which A=0.60dB. And I can think of another in which A=
5.2dB. The definition I have used for loss in those cases is
A=-10*log10(P1/P2), where P2 is the power delivered to the (line+load)
and P1 is the power delivered to the load, with steady-state
excitation. The answer, given that definition, never depends on
source impedance of the driving source. Of course it could with a
different definition, for example involving the maximum available
power from the source, but that just confuses the issue by lumping
"(source) mismatch loss" with acutal line loss, as has been pointed
out before.

Cheers,
Tom

And, it gets even better!! As most homes now use EITHER Plastic, or Copper pipes.
Obviously, Plastic is an insulator. What many DON'T appreciate, however, is that COPPER PLUMBING (to the water main) most likely (and , if it doesn't , should be installed) has Insulated UNIONS ! These are placed on the feeds to prevent electrolysis! With them, copper pipe will survive 20 + Years, before being eaten thru. Without, more like 5-8 years!! And, even in OLDER HOMES , with Iron pipes, if the lines have been replaced, you may encounter this !
Word to the wise: sink a 8 FOOT ground rod!! Better to be safe than sorry-- Jim NN7K

[snip]

I like that definition best of all in a theoretical setting... but be
prepared...
there are many others to be found in the literature.

Even though I like the definition you have shown above, I find the
definitions...

a = v + Zo*i and b = v - Zo*i

To be very convenient in practice since they correspond to a very easy to
understand, visualize and manipulate single Operational Amplifier
reflectometer
circuit.

As long as the relationship between v and i and a and b are simple linear
combinations
without singularities, i.e. the transformation matrix M which allows you to
transform between
the [a, b] vectors and the [i, v] vectors is non-singular then you are just
fine, as long as
you remain consistent with your initial definition. You can perform
reliable and accurate
Engineering with any definition of the "waves" [a, b] that are a suitable
linear combination of the
"electricals" [i, v].

[snip]

Yes I did. I guess that you missed that post.

I'll paste a little bit of that posting here below so that you can see it again.

[begin paste]
We are discussing *very* fine points here, but...

[snip]
ratio of the reflected to incident voltage as rho = b/a would yeild the usual formula:

rho = b/a = (Z - R)i/(Z + R)i = (Z - R)/(Z+ R).

In which no conjugates appear!

Now if we take the internal/reference impedance R to be complex as R = r + jx then for a "conjugate match" the unknown Z would be the conjugate of the internal/reference impedance and so that would be:

Z = r - jx

Thus the total driving point impedance faced by the incident voltage a would be 2r:

R + Z = r + jx + r - jx = 2r

and the current i through Z would be i = a/2r with the voltage v across Z being v = a/2.

Now the reflected voltage under this conjugate match would not be zero, rather it would be:

b = (Z - R)i = ((r - jx) - (r + jx))i = (r - r -jx -jx)i = -2jxi = -2jxa/2r = -jax/r

and the reflection coefficient value under this conjugate match would be simply:

b/a = rho = - jx/r

Thus I conclude that, under the classical definitions, when one has a "conjugate match" [i.e. maximum power transfer] the reflected voltage and the reflection coefficient are not zero.
:
:
In summary:

Under the classical definition of rho = (Z - R)/(Z + R) rho will be not be zero for a "conjugate match" and in fact there will be a "residual" reflected voltage of -jx/r times the incident voltage at a conjugate match. The only time the classical definition of rho and the reflected voltage is null is for an "image match" when the load equals the reference impedance.
:
:
Unless one changes ones definition of the reflected voltage/reflection coefficient to utilize the conjugate of the internal impedance as the "reference" impedance then the reflected voltage is not zero at a conjugate match. End of story.
[snip]

What about Ramo and Whinnery's forward Poynting vector and reflected
Poynting vector? Why do you choose to ignore them?

> Not necessarily. Only once the line has been charged, does the energy
> move back and forth between the quarter wave points, while not
> crossing them.

That has been shown to be a false assertion regarding component waves.
There is no impedance discontinuity to cause any reflections. Therefore,
the waves do not move back and forth. Do you really believe that the
energy in a bright interference ring is trapped inside the ring? Get
serious!

There is no NET energy flow. There is plenty of component energy
flow as defined by Ramo & Whinnery's forward Poynting vector and
reflected Poynting vector. Why do you continue to ignore those
vectors? Why do you continue to ignore the wealth of knowledge
contained in light interference patterns?

[snip]

I agree, you are absolutely right!

One should not take advice from the optics folks, simply because their instrumentation when compared to that of our RF types is defficient.

In our RF applications we have no difficulty making "coherent" measurements. We can measure and utilize all of the phase information relatively easily at RF frequencies.

The same is not true for optical frequencies. The laser was only invented a couple of decades ago... there are no optical phase locked loops even today, etc... Most optical folks use the incoherent "power" measurements only because of the great difficulty of making coherent phase measurements with optics.

Acutally the optics experimental folks have a lot to learn from we low frequency folks who have fully explored the use of coherent phase aware metrology!

I am afraid that Cecil has been seduced by the "age" of some of the optical publications into believing that the opticians are ahead of the elecricians, but that is simply not so... we electricians know lots more about wave dynamics than opticians.

Aside: With the singular exception of quantum mechanics, and quantum electrodynamics [QED] which of course at the low intensity photon-at-a-time level of interaction takes us miles away from waves and classical electrodynamics and into particles, entanglement, etc..

> where the forward Poynting vector and reflected Poynting vector
> are out of phase.

This emphasis on NET seems to be the place where the difficulties
begin. An (ideal) voltmeter placed at a voltage minima on the line
indicates a voltage of 0 volts. You appear to be saying that
despite this indication of 0, there is actually voltage present.

This contention leads to a number of questions related to voltmeters:
- when I use a voltmeter to measure the voltage in a circuit,
how do I know when an indication of 0 means 0?
- how do I know when an indication of 0 means there are
really a number of voltages which sum to 0?
- how do I determine what these voltages are which sum to 0?
- if it indicates other than 0, is it really indicating a
number of voltages which sum to the result?
- how do I determine what these voltages actually are?
- can voltmeters be trusted at all?
- when?

In my world, voltmeters indicate volts. There is no need for
second guessing.

Until this very fundamental difference is settled, there is
no value in examining the remaining steps.

Seems to me that the sinusoidal standing wave with minima and maxima
at the quarter wave points can only arise with single frequency
sinusoidal excitation of the line. Are there other signals which
will produce this result?

I haven't used them because I don't need them to arrive at an answer.
Basic electricity, a dash of circuit theory, a bit of knowledge of
trigonometry, some basic calculus and the ability to think is all
that is required.

Why make the solution more complex than necessary?
Just to scare off the neophyte?

> > Not necessarily. Only once the line has been charged, does the energy

In this context, we are discussing transmission lines. I make NO
assertions about light, how rings happen, or don't, or whether the
theory and practice of optics is in way analogous to what happens
on a transmission line.

Transmission lines and their understanding can stand on their own
without the help of optics.

Source record: 109594

With the downturn in the solar cycle and worse days ahead, I'm faced with operating on the lower hf bands. 20M has gotten to be very hit or miss wrt propagation and it seems that more and more dx is happening on 40 (with some on 30). I have a 40M dipole up about 30 ft or so, but that really doesn't cut it.

I know that this is like a discussion about "what's the best color", but what antenna systems will work well on 40M, maybe even 80M, that I could mount either on the ground or up no higher than 30 ft? I need to at least get some general direction on this from an experiential data set rather than starting with the ads in QST or CQ.

Hi Keith,

We covered this before. The NET 0 "could be" the result of a
bajillion volts and -bajillion volts. Now you couldn't possibly
ignore a bajillion volts now, could you? ALL things are possible when
we have a zero to rummage up arguments that revolve around what "could
be." It takes only a slight rhetorical slide to become "is."

You certainly would need a perfect voltmeter to withstand the
potential fields nearby. ;-)

How about a Moxen rectangle? Very easy to build.
If you are familiar with the layout.....
900 MHz =
12 wire
Driven element length of 4.68" plus 'legs' of 0.56"
Reflectors element of 4.68" plus 'legs' of 0.91"
Gap between the 'legs' of 0.28"

If you're not familiar, do a Google search and you will probably find
a dimensions calculator. If not, tell me your exact frequency and
I'll calculate them for you.

On the surface, this sounds like a stupid question, but how do I know my shortwave wire dipole antenna is picking up all it can?

If I live in the St. Louis Missouri Area, is there a list of stations X, Y, and Z that I should be able to pick up? (thinking shortwave here, not local stations)

And if so, If I can pick up station A from Egypt, station B from Japan, and station C from Moscow, then I'm doing really good?

Just wondering.

Thanks..

Just look at ground around the antenna. If you do not see any stations rejected and dropped in the mud, then your antenna is doing fine job and picking up everything it can.

Get some books on antennas and propagation, it is fascinating reading and will answer many questions and provide food for some experimentation in your quest in hearing everything.

Hi Walter,

This is a tough nut to solve lacking comparisons.

So, it must be done by comparison. One way to judge band conditions is to maintain a log of familiar and fairly constant sources. Among those, WWV and WWVH (or CBUT in Canada, and other time signals throughout the world) offer that across many frequencies. However, this goes only so far unless you manage to DX those remote time standards (WWV is not very far away in the scope of things).

There are also stations known as beacons transmitting in the Amateur frequencies (as well as commercial beacons) that transmit for this very purpose. Use a web search engine to find beacon forecasting software (try using the term Tabor, who is one source).

All this aside, it says nothing of the inherent sensitivity (or lack of it) for your receiver. Barring your having been hit by high voltage due to a nearby strike of lightning, you stand every chance of having all that you are going to get (the receiver will be fairly deaf otherwise).

Right now I am listening to Radio New Zealand that comes in with broadcast quality, you may not be so lucky, but on the flip side, you may get Europe with far more ease than I do (the North magnetic Pole is the pits for the Pacific Northwest). VOA, BBC, CBC, Deutsche Welle, Radio Nederland (actually out of the Caribbean), Radio Habana, Radio South Africa, Radio Australia, HCJB, NHK, Radio Moscow, and others are also often quite strong. Get to know their schedules

through the day and night, and visit frequently while taking notes in a log. Patterns should begin to emerge (and then shift as the year progresses, and shift again as the sunspot numbers fall).

Radio shack discone? Fairly broadbanded...A simple ground plane will
work fairly well for most freq's. Depends on the range you want to
cover. A GP cut for hi-band VHF will do a passable job on UHF as a
psuedo 5/8 wave of sorts. Most public service signals are fairly
strong unless you are in the sticks, so it should't be real critical.

There are actually two voltages present of equal amplitude and
opposite phase. Their phasor sum is zero volts.

> - how do I determine what these voltages actually are?

|Vfwd| = Sqrt(Pfwd*Z0) |Vref| = Sqrt(Pref*Z0)

If the voltmeter reads zero, these two voltages are equal in magnitude
and opposite in phase. Do you know how to sum two phasor voltages?

You will never understand the present topic unless you understand that
EM wave interference doesn't affect the flow of energy in the individual
waves. That is true for light and RF.

It could be but it's not. The NET 0 is the result of Pfwd=Pref
Thus, Sqrt(Pfwd*Z0) = Sqrt(Pref*Z0) and when they are 180 deg
out of phase, the net voltage is zero.

I should have added: "in the absence of a physical impedance discontinuity."
If a physical impedance discontinuity exists, then of course, the flow of
energy in the individual waves is affected by reflections.

Hi

One possible could be ground mounted vertical array.
There are triangle and quad (four "corner") constructions.
Triangle gives 6 switchable directions and some gain and FB but
requires radial wires to be effective.

QST Aug -72 had a quite extensive article of 7MHz triangle array.

Just use a PVC elbow or "Tee" on bottom, then use another section of
PVC to mount to the mast using clamps. Works well and if you want use
some wood dowel inside for added strength.

Thank you for the replies Gents. I am trying to get a handle on this modeling stuff and this helps. I will ask another!
Quote--
"Unless iron filings or crushed ferrite are mingled with the soil, the permeabilty of this 1-metre cube of space will be unity and can be ignored.
Such mixtures are not known in the natural world." -- unquote

I was in Iqaluit last year and when I put the Globalstar antenna on the ground the magnets picked up a huge amount of filings, like in high school when you did that magnet class. How would that affect your antenna? Having such a conductive ground would be good would it not? Better ground plane? Of note the rock all around that area was like that, huge iron content as it was orange like in it's colour.
Brings me to another question. To operate from a fjord like area on the bottom would really kill your signal would it not? The rocks would suck up all your sig with their high iron content would they not, and you would have a devil of a time getting over the top right?

4265. Re: How do I know my Antenna is doing well???

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-27 05:25:01 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vkog59kp6i2n58@corp.supernews.com>
Source record: 109610

A simple test you can make is to tune to a frequency where there's no station, and disconnect the antenna from your radio. Repeat the test on various frequencies scattered around the range you listen on. If there's any frequency below about 30 MHz where the noise level doesn't drop when you disconnect the antenna, then you can benefit from antenna system improvements. These might involve an antenna tuner, lower loss feedline, another dipole or dipoles (which could share the same feedline), traps in your existing dipole, or some combination.

If the noise level drops at all frequencies when you disconnect the antenna, you can't improve the dipole itself except by making it higher. As a general rule, the higher you put it, the more it will favor distant stations and the less it will respond to noise (and signals) coming from lesser distances. You might benefit from something like a desktop loop which you can rotate to null out some particular source of noise coming from a single direction. And it's often possible to reduce locally generated noise without much effect on distant stations, if that's a problem. Other than that, the only improvement you can make is to make the antenna more directional. This would take a more elaborate antenna system than just a dipole, and it would have to be rotatable if you don't want some directions to suffer.

Hm, this has me puzzled. Assuming a purely real Z0, you're taking the square roots of two purely real quantities, each of which can have two values, and speaking of a phase angle between them. Where in the process did they pick up phase information? Or do you just mean when one is the negative of the other? If so, how do you tell -- each has two roots, that is, Sqrt(Pfwd*Z0) can be either positive or negative, and so can Sqrt(Pfref*Z0). How do you know when one is the negative of the other?

Here I'll assume that you've defined a and b as equalling the forward
and reverse voltages in a transmission line, which is a different
definition than in your other posting. With that definition of a and b,
and if R is the transmission line characteristic impedance, then the
equation is valid for a transmission line, and ok so far. Otherwise,
you're talking about something other than a transmission line, so the
"proof" doesn't apply at all.

> In which no conjugates appear!

So the load impedance is the complex conjugate of the transmission line
characteristic impedance. Ok.

>
> Thus the total driving point impedance faced by the incident voltage a would
> be 2r:
>
> R + Z = r + jx + r - jx = 2r

Here you've lost me. a is the forward voltage in the transmission line.
What can be the meaning of its facing a driving point impedance? The
forward wave sees only the characteristic impedance of the line; at all
points the ratio of forward voltage to forward current is simply the Z0
of the line. So I don't believe that it sees 2r anywhere.

This is where I'm stuck. If you can show where along the line the
forward voltage wave "faces" 2r, that is, Vf/If = 2r, I can continue.

4268. Reflection Coefficient Smoke Clears a Bit

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-27 06:18:09 UTC
From: radio913@aol.com
Message-ID: <1d15af91.0308262218.7e553fd5@posting.google.com>
Source record: 109613

Hello,

Actually, my first posting:

Reflection Coefficient =(Zload-Zo)/(Zload+Zo)

was right all along, if Zo is always purely real. No argument there.

However, from Les Besser's Applied RF Techniques:

"For passive circuits, 0<=[rho]<=1,

And strictly speaking:

Reflection Coefficient =(Zload-Zo*)/(Zload+Zo)
Where * indicates conjugate.

But MOST of the literature assumes that Zo is real, therefore
Zo*=Zo."

This is why most of you know the "normal" equation.

And then i looked at the trusty ARRL handbook, 1993, page 16-2,
and lo and behold, the reflection coefficient equation doesn't have a
term for line reactance, so both this book and Pozar have indeed
assumed that the Zo will be purely real.

Here's a website that describes the general conjugate equation:

http://www.zzmatch.com/lcn.html

Additionally, the Kurokawa paper ("Power Waves and the
Scattering Matrix") describes the voltage reflection coefficient
as the same conjugate formula, but he rather foolishly calls it a
"power wave R. C.", which when the magnitude is squared, becomes the
power R. C.

Email me for the paper.

As Reg points out about the "normal" equation:

"Dear Dr Slick, it's very easy.

Take a real, long telephone line with Zo = 300 - j250 ohms at 1000 Hz.

(then use ZL=10+j250)

Magnitude of Reflection Coefficient of the load, ZL, relative to line
impedance

= (ZL - Zo) / (ZL + Zo) = 1.865 which exceeds unity,

and has an angle of -59.9 degrees.

The resulting standing waves may also be calculated.

Are you happy now ?"

Reg, G4FGQ

Well, I was certainly NOT happy at this revelation, and researched it until i understood why the normal equation could incorrectly give a R.C.>1 for a passive network (impossible).

If you try the calculations again with the conjugate formula, you will see that you can never have a [rho] (magnitude of R.C.) greater than 1 for a passive network. You need to use the conjugate formula if Zo is complex and not purely real.

How could you get more power reflected than what you put into a passive network(do you believe in conservation of energy, or do you think you can make energy out of nothing)? If you guys can tell us, we could fix our power problems in CA!

Thanks to Reg for NOT trusting my post, and this is a subtle detail that is good to know.

Slick

One indication of your antenna's effectiveness (on HF) is if the receiver's noise output increases
when the antenna is connected. If so, the antenna is providing enough signal to overcome the
receiver's internal noise. Effectiveness on a particular station's strength can only be judged by
comparison with another antenna at the same site or with another receiver and antenna at a nearby
site. What you may be able to hear at a given time on a given frequency depends a lot on antenna
directivity and propagation.

Source record: 109616

These are the reply comments of Ameren Energy Corporation:

http://gullfoss2.fcc.gov/prod/ecfs/retrieve.cgi?native_or_pdf=pdf&id_document=6514683314

They outline why power lines are excellent RF transmission lines that radiate only at points of "discontinuity."

And, for those that may wonder: there was a typo in the formula, but the calculations that follow had been done correctly. (Too bad they used the typo to do all of their calculations incorrectly...)

I re-ran the antenna models and easily found the gain that the ARRL paper had documented. (The easiest wa to do that is to run a 3 D model in EZW, then check the box for a 2D display. It will display the plot of maximum gain). Maybe they can sign up for the ARRL modeling course.

Those that want an easy list of the links to the industry and organizational filings on BPL can go to:

http://www.arrl.org/~ehare/bpl/hyperlinks.html

I wrote:
"As energy can`t be destroyed it had to be reflected by a hard short or open." Keith replied:
"Or just stopped and stored."

Wave energy is energy in motion. No motion, no waves.

Keith also wrote:
"All of this is easily visualized by observing the amplitude of the P(t) function at various points along the line."

Power as a function of time has the same amplitude in the forward wave everywhere along the line. Same is true of the reflected wave. Interference as demonstrated by standing waves has no effect on this.

Keith wrote:
"I would strongly suggest that no energy crosses these points in the line where the voltage and current are always zero since p(t) is always zero."

See my comment above on power as a function of time. Keith erred in saying "points in the line where the voltage and current are always zero", as where SWR volts are zero, amps are max, and vice versa.

I wrote:
"If energy were turned around before it reached the end of the line, nulls more distant from the source than the turnaround point would not exist."

Keith wrote:
"Not so,---."

There is no argument that can make wave interference where there are no waves. In a lossless line, pre-existing waves could circulate forever. But, our discussion relates to effects on actual lines.

Keith wrote:
"Try visualizing how a step function charges the line."

Totally irrelevant. SWR nulls are the result of phase opposition at specific points produced by alternating waves. A step function changes only when it starts or stops. Only during the changes does Zo apply unless a line is terminated in its Zo. In this case there`s no reflected wave to make a null. As Reg once said, "If your line were infinite in length, you could measure Zo with your ohmmeter.

Keith wrote:
"I do not find that step 7) is in error."

Step 7) declares power is zero at quarter wave points where volts or amps are zero in the standing wave pattern.

Power flow does not stop at an actual short or open in a line. It merely changes direction. At zero volt or amp points, where there is no actual short or open, no reversal of direction occurs. Power flow is affected in no way by standing wave nulls or maxima where no impedance discontinuity exists.

Energy exists in every SWR null. It is in the two waves which produce the null as these experience no change in energy due to standing waves.

Best regards, Richard Harrison, KB5WZI

If you have the horizontal room (70 feet, sounds like you might) and at least 35 feet up, why not a Half Square for 40? Doesn't need radials, it's an 'upside down' phased vertical array with some gain and a good TOA. Be aware however, it is somewhat directional. Easy to make on your own, also cheap and there is a lot of info on the Web. I have one for 20 meters (very modest with the antennas here) and it works a lot better than my R5 vertical and full sized G5RV.

4275. MFJ 989c tuner question

Message-ID: <19apkvsl01ke7rmeqge8sj4ooo0uhdjfvf@4ax.com>
Source record: 109587

I'm tuning up a dipole with the 989c, using it for the first time in several years.

Does maximum inductance occur with the reference counter at 000, and minimum inductance at 125?

The MFJ manual I downloaded contradicts itself on this point, and I'd like to get it clear.

Thanks,

Bob

Keith wrote:
"-how do I determine what these voltages actually are?"

You measure the power in either direction using a wattmeter containing a directional coupler. The volts, amps, and power flowing each direction are the same. That`s why you have zeros.

Then, P = Esquared / Zo, so E = sq rt (P)(Zo)

Keith wrote:
"Are there other signals which would produce this result?"

A short-circuit produces a voltage inversion. The plus volts and the minus volts make a zero in a short.

Imagine a couple of identical positive pulses separated by some distance and traveling in the same direction along a long transmission line which has a short approached by the pulses. When the first pulse hits the short it is inverted and reflected to travel back toward its source as a minus voltage pulse.

When the first pulse encounters the second pulse they disappear at the instant of coincidence, but otherwise, travel on their merry ways. What happens at coincidence is transfer of the energy associated with volts to the energy wave associated with amps as energy can`t be obliterated while the volts disappear.

Andrew, Just enter in EZNEC :

Conductivity = 0.1 milli-Siemens,

(Or Resistivity = 10,000 ohm-metres.)

Permittivity, or dielectric constant K = 4,

and you will get results just as accurate as EZNEC is able
to provide with more usual values of ground 'constants'.

At HF, in the case of granite, as discussed below, the
controlling factor is permittivity K and any reasonable
very high value for resistivity will suffice. Granite is a
fairly low-loss material. Roy, you should have more
confidence in your 'baby'.

Soil, or whatever you are blessed with, has an
impedance Zs = Rs - jXs. It can be modelled to the
first order of accuracy by a resistance in parallel
with a capacitance.

Rs and jXs are the equivalent series components.

Soil resistivity is that measured between opposite
faces of a 1-metre cube of the material. Easy to
visualise and understand.

Capacitance is that measured between a pair of
1-metre square plates spaced 1-metre apart,
multiplied by the permittivity of the material.

Unless iron filings or crushed ferrite are mingled with the soil, the
permeabilty of this 1-metre cube of space will be unity and can be ignored.
Such mixtures are not known in the natural world.

Soil loss occurs due to current flowing in the soil
through Rs. Note carefully that Rs, a series
component, reduces as frequency increases. And
so soil loss decreases with increasing frequency.

Permittivity K increases fast with water content. In
solid rock moisture content is negligible and K is
that of the material itself, crudely 3 to 7. Mica is
a rock, K = 7. Quartz, another rock, K = 4.
Sahara sand has a lot of dry air in it, K = 3.

Lumping all sorts of backyards together, soil impedance is resistive below 1 or 2 MHz with a small -ve angle. Around 5 to 12 MHz impedance has an angle around 45 degrees. At 30 MHz impedance is that of a lossy capacitor, but low in value and therefore a good reflector. At VHF soil impedance is very low, has a high negative angle, and is an efficient low-loss reflector.

The best reflectors are those with a small impedance magnitude relative to 377 ohms combined with an impedance angle approaching -90 degrees. The angle of incidence is also in there somewhere. But don't forget skin depth in the soil is quite shallow at VHF and only the top thin surface layer may be involved.

If anybody intends to do any calculations it's far more convenient and meaningful to work in practical terms of ohm-metres. Milli-Siemens sounds pseudo-scientific and is not particularly impressive.

The capacitance between two 1-metre square plates, spaced 1-metre apart, is 8.8 picofarads. Doesn't seem very much. But with an ordinary garden soil permittivity of 15, the impedance at 7 MHz is - j170 ohms. And with an ordinary garden soil resistivity of 170 ohms-metres we have an angle of -45 degrees.

Two programs, EARTHRES and RADIOETH may be of interest. Download in a few seconds from the following website and run immediately. In addition, program SOILSKIN calculates skin depth in soil.

Source record: 109526

What is missing here, IMO, is that the physics of energy flow has not been adequately explained. Cecil provided a reference to it but did not elaborate for the general readership.

The energy in forward and reflected waves has been well documented for many years. From Kraus, Electromagnetics, McGraw Hill, 1953, Chapter 9, Section 9-13, "Energy Relations in a Standing Wave":

EQ 9-145 We = 2eEo^2[cos^2wt*sin^2Bx]

EQ 9-147 Wm = 2uHo^2[sin^2wt*cos^2Bx]

Note: The energy in the E field [We] is a function of the sin^2(Bx). The energy in the H field [Wm] is a function of the cos^2(Bx).

You will remember from trigonometry the the maxima [or minima] of a sin and cos are displaced by 90 degrees. Conclusion: when the E field is zero the H field is maximum; when the H field is zero the E field is maximum. Ergo! Energy is conserved and propagates through the zero E field as an H field; also, when the H field is zero the energy is in the E field. This is what Cecil is referring to when he refers to the Poynting vector.

It is analogous to a parallel tuned circuit. When the instantaneous voltage across the capacitor is zero we don't claim there is no energy in the circuit. We know that the energy is stored in the inductor. Conversely, when the instantaneous current in the inductor is zero we don't claim there is no energy in the circuit. We know the energy is stored in the capacitor.

In a TEM wave the energy cycles between the E field and the H field and the energy components are 90 degrees out of phase.

> Sqrt(Pfref*Z0). How do you know when one is the negative of the other?

V^2/Z0=P is a well known equation (so is I^2*Z0=P). These are *RMS* values.
So the RMS voltage is V = Sqrt(Pfwd*Z0). Root Mean Square AC voltages are
equivalent to DC voltages in power dissipation and are generally considered
to be positive values because they are the sum of squared terms. We can turn
those RMS voltages into phasors by adding the phase angles. When Vfwd+Vref = Vmax,
Vfwd and Vref are in phase (at the SWR voltage maximum point). When Vfwd+Vref = Vmin,
Vfwd and Vref are 180 degrees out of phase (at the SWR voltage minimum point).
Vmax/Vmin = VSWR. Please feel free to pull my leg again anytime. :-)

It seems iron, in its magnetic form, is a little more common in soil than I thought.

As just described, our 1-metre cube of space containing garden soil has higher values of conductivity and permittivity than an empty space. When associated with a grounding system the effect of increased permittivity is to much reduce the velocity of propagation of em waves through the soil and along any wires buried in it.

A quarter-wave of buried wire may have a physical length only 1/6th of a quarter-wave of wire in free space. The velocity along a radial wire just lying on the surface of good soil is reduced to only 1/2 of the free-space value and should be pruned accordingly. Old-wives and Handbook editors please note.

A high content of magnetic iron in the soil would reduce propagation velocity further still in the proportion 1/Sqrt(Mu). How this would change the loss-distributing effectiveness of radial wires I have no idea. My back yard contains no iron and I have no intention to dig in 10 or 20 tons of iron filings just to see what happens on the S-meter.

According to Adler, Chu, and Fano, "Electromagnetic Energy Transmission and Radiatin", John Wiley, 1960, (60-10305),
when they talk about lossy lines, and say that Zo is complex in the general case, they come up with a maximum value for the reflection coefficient of (1 + SQRT(2)). Eq 5.14b. Remember, it is a lossy line; so, the reflected voltage gets smaller as you move away from the load. Somebody might want to check this out, in case I misunderstood something. BTW, the three authors were all MIT profs.

The problem is in leaping to the conclusion that a reflection coefficient greater than one means that more energy is coming back from the reflection point than is incident on it. It's an easy conclusion to reach if your math skills are inadequate to do a numerical analysis showing the actual power or energy involved, or if you have certain misconceptions about the meaning of "forward power" and "reverse power". But it's an incorrect conclusion. Then, having come to the wrong conclusion, the search is on for ways to modify the reflection coefficient formula so that a reflection coefficient greater than one can't happen and thereby disturb the incorrect view of energy movement. It's simply an example of faulty logic combined with an inability to do the math. Adler, Chu, and Fano do understand the law of conservation of energy, and they are able to do the math.

My expeience with using T's and elbos with PVC is that it weakens the structure. Dont really like PVC for doing what you are talking about and prefer to design antennas that will be self supporting and cand withstand the elements. That being said, There are PVC couplings designed for transistioning from threaded metal pipe to PVC . For a while I had an antenna similar to your discription that was set uo as follows. 2 inch galvanized pipe for a mast, pull box on top of that ,2 meter colinear array above that in PVC. Feed line entered through a compression fitting in the cover of the pull box. This worked well for about 2 years then the sun began to cause severe deterioration of the PVC.

How convincing are A, C and F? Nobody's ever heard of 'em. What makes you think the trio are right? Or have you worked it out for yourself?

Reminds me of the advert "Can 1 million housewives be wrong ?" (in their choice of bathroom cleaner). ;o)

By the way, you've told us only half the story. What's the value of the load impedance which maximises the reflection coefficient?

Regards, Reg, G4FGQ.

PVC pipe is not made for use in the sun. The UV rays weakin the tubing. It
will stand up beter if it is painted or coated so the UV rays will not get
to it.

We can unless Sqrt(P*Z0) equals a bajillion volts which it usually
doesn't. These values are all inter-related. A 200W transmitter
will pour Sqrt(200*50) = 100 volts RMS into a 50 ohm load. That's
a no-brainer. Why do you act like it is a far out big deal?

>Why do you act like it is a far out big deal?

Hi Cecil,

Are you now trying to convince us that a bajillion volts *RMS* meeting
-bajillion volts *RMS* is NOT NET 0? Those are merely the points
where the forward Poynting vector and reflected Poynting vector
are out of phase. We are dealing with component energies. The NET
energy is zero. The component energies are not zero. This would seem
to conflict with much of your wave mechanics for the last 6 months.
Shirley you cannot deny the impact of a bajillion volts *RMS* simply
because your current argument doesn't need that solution, can you? (I
guess you can.)

However, that is not to say that we didn't notice that rhetorical
slide from "could be" to the firmer "is." We can specify these
bajillion volts *RMS* with a phase of a mega-bajillion degrees (with
deliberate care to avoid problematic 179 or 181 degrees) to suit any
opportunistic need. ;-)

[snip]

Hi Yuri.

Well Indialantic By-the-Sea is a small town [pop ~2500] on the barrier
island about
25 miles South of Cape Canaveral, just opposite Melbourne on the mainland.

On the East side our island faces the Atlantic Ocean beaches, and on the
West it
faces the two mile wide Indian River Lagoon. The Lagoon is partly salt
water since
it has inlets from the ocean every few miles but with mainland rivers also
flowing into
the lagoon. The lagoon is a very diverse ecosystem and supports both salt
and fresh
water denziens simultaneously, for examples: manatees, alligators,
dolphins, trout,
snook, shrimp, all kinds of shellfish, etc... a fishermans, and pelicans,
and ospreys
fishing paradise!

The island is about one mile wide West to East at the town and so
Indialantic By-the-Sea
occupies about one square mile between the Indian River Lagoon and the
Atlantic Ocean,
hence the name "Indialantic".

My current QTH is a couple of hundred feet from the Atlantic ocean beach...
a great
location for antennas and propagation, and a bad location for tropical
windstorms! I

am planning a tower with quad(s) to be erected soon.

I think the fundamental problem here is that the concept of waves of average power necessarily assumes nice, smooth, non-varying "waves" of DC (average) power flowing along the line. When two of these "waves" occupy the same space, they necessarily combine to form another smooth combination net "wave". There's no way to account for the reality that power and energy are *not* flowing in smooth, DC waves, but rather as a time-varying function. Power is flowing back and forth each cycle, and energy is moving into and out of storage each cycle. The time-varying information is thrown away as soon as the average is taken, and it can't be retrieved. So if all you can envision is waves of average power, it's impossible to understand what's really happening with respect to power and energy along the line. You simply don't have the information necessary to envision or understand it.

[snip]

I appologize if I am "going to fast" for the limitations inherent in
NewsGroup postings.

Let me take it a little more slowly here...

To see that there is essentially no difference between my (apparently two)
different
definitions of the incident and reflected waves a and b, consider the
following scenario
of an actual transmission line having surge impedance [characteristic
impedance] Zo.
Let Zo be in general complex. i.e. Zo = sqrt[(R + jwL)/(G + jwC)] where R,
L, G,
and C are the primary parameters of R Ohms, L Henries, G Siemens, and C
Farads
per unit length.

Now at any particular frequency w = 2*p*f you will find that this general
complex
surge impedance Zo evaluates to a complex number, say Zo(jw) = r + jx.
Later
let's let r = 50 Ohms and x = 5 Ohms so that we can work out a numerical
example.

Consider either a semi-infinite length of this Zo line, or even a finite
length of the Zo line
terminated in an impedance equal to Z0. I am sure that you will agree that
both the
semi-infinite Zo line or the finite length Zo line terminated in Zo have the
same
driving point impedance namely Zo.

Now excite this semi-infinte Zo line by an ideal generator of open circuit voltage
Vi = 2*a behind an impedance equal to the surge impedance Zo. In other words
this is a Thevenin generator of ideal constant voltage 2a behind a complex impedance
of Zo. And so... since an ideal voltage source has zero impedance, the termination
at the source end of this semi-infinite Zo line is Zo, and so the line which has a
driving point impedance of Zo is terminated in Zo. Thus the port or reference plane
between the generator and the semi-infinite line is an "image match" point.

For reference, a rough ASCII style schematic of this situation would be as follows.

Generator = Vi = 2aVolts -> generator impedance Z0 -> impedance Zo of semi-infinite line.

Clearly the the generator impedance of Zo and the line's driving point impedance of Zo
constitute a voltage divider hanging off the generator with open circuit volts Vi = 2a Volts,
and since Zo = Z0 they divide the generator voltage, which equals 2a volts exactly by 2, and
so the voltage across the input of the semi-infinte line is exactly a volts. This a is the incident
voltage wave of the Scattering Formalism and it is exactly the same as the classical forward
voltage for transmission lines. Note that it is exactly half of the generator's open circuit volts.
i.e. the voltage across the perfectly terminated [image matched] line is exactly a Volts or 1/2
of Vi Volts. [Aside: That is why I said in an earlier post that your forward wave and my
incident wave only differ by a factor of two! They are really no different it's only a scale
factor. You can compensate as I have by calling the Zo generator voltage 2a, but for
simplicity I often just call it a to eliminate the factors of 2 that occur all over the place. Sorry
if that is confusing, I'll try not to do that any more. :-).

Now everybody knows and everybody will agree that at the junction of the Zo line
terminated in Zo [NOT a conjugate match] where the Thevenin generator is connected
to the semi-infinite Zo line there is an image match AND there will be no reflected voltage
waves. What is more since the Zo line is semi-infinite, or the alternative of a finite length

and terminated in Zo at the far end, there will be no reflections at the "far end" either. i.e. in this
situation there are no reflections and the incident wave "a" just propagates into the line and
there is no reflected wave b to interfere with it. Note that this does not mean that maximum
power is transmitted into the line. You and I both agree that when a generator is image
matched [Cecil likes to call "image match" a Zo match] that in the general case of complex
Zo maximum power is not transferred but there is NO reflected voltage when measured
with a reflectometer which uses Zo as it's reference impedance.

This scenario at the Zo generator driving the Zo line is the same situation found when you cut
into an infinite length of Zo line and insert a reflectometer with reference impedance Zo,
the reflectometer will read out the reflected voltage b as:

b = rho*a = (Zo-Zo)/(Zo+ Zo) = 0 Zero, nada, nil... no reflections.

Now lets do a simple numerical example.

Consider that at some frequency the surge impedance evaluated to say Zo = r + jx = 50 + j5
Ohms and that we set the generator open circuit voltage to be Vi = 2a = 2 volts. Thus the "incident
voltage wave is a = 1 Volt.

The maximum power available from this Zo generator will occur when the load, call it Z, on the
generator is a conjugate match to the generator impedance Zo. Thus for maximum power
transfer Z must be the complex conjugate of Zo, i.e. we must let Z = 50 - j5, to extract maximum
power not Z = 50 +j5.

Under these conjugate matched conditions, the total impedance faced by the generator is the sum of
its' internal impedance Zo and the external Z, i.e. the total impedance is

Zo + conj(Zo) = 50 + j5 + 50 - j5 = 100 Ohms

And so the generator impresses it's 2 Volts of open circuit volts across the resulting totalof 100 Ohms
supplying a current of I = 2/100 = 20mA to the real part of the load of 50 Ohms for a maximum
power of:

Pmax = I*I*R = 0.02*0.02*50 = 0.0004*50 = 0.02 = 20 mWatts.

Under this conjugate matched condition, where the maximum power of 20mW is transferred, if we
use the classical definition of rho = (Z - Zo)/(Z + Zo) with Z = 50 - j5 and Zo = 50 + j5
we get:

rho = b/a = ((50 - j5) - (50 + j5))/((50 - j5) + (50 + j5)) = (-j5 - j5)/(100) = -j10/100 = -j/10

Since the incident wave is a = 1 Volt, then:

b = rho* a = -j/10 Volts.

With a conjugate match, and using the classical definition of rho, as measured by a reflectometer using
Zo as it's reference impedance, there will be a reflected voltage of magnitude 0.1 Volts, or one tenth of a volt at a phase lag of ninety degrees.

It is interesting to see what value of reflected voltage would be indicated by a Bird Model 43 in
this circumstance of a perfect conjugate match.

A Bird Model 43 uses an internal reference impedance of R = 50 Ohms and it implements the "classical" definition of rho. i.e. The Bird Model 43 calculates the reflected
voltage b as b(Bird):

b(BIRD) = rho * a = (Z - 50)/(Z + 50) * 1 = (50 - j5 - 50)/(50 - j5 + 50) = -j5/(100 - j5)

Actually the Bird cannot indicate phase angles, rather it just computes the approximate magnitude
of the reflected voltage which in this case would be

|b(Bird)| = 5/sqrt(100*100 + 5*5) = 5/sqrt(1025) = 0.156 Volts.

Compare this to the magnitude of the "true" reflected voltage which is 0.1 Volts as computed by a true reflectometer which used Zo as its' internal reference impedance.

And so... contrary to popular opinion, the Bird does not indicate zero reflected power when it is inserted into a perfect conjugate matched [maximum power transfer] situation when the Zo of the system is not a pure 50 Ohms!

Now if we choose to use a different definition of rho, say the one proposed by Slick why then we will get different results for the reflected voltage, in fact with his somewhat erroneous formula for rho he will read rho as zero in the conjugate matched situation. However. even though one can use any definition as long as one consistently uses it in all theoretical developments and measurement, as in one of my other posts to this thread, I do not believe Slick's or anybody elses re-definition of rho to be approved by "Mother Nature".

Mother Nature uses rho = (Z - Zo)/(Z + Z0) simply because that is the reflection coefficient that exists at any point along any infinitely long transmission line of constant surge impedance Zo where looking to the right and to the left at any point in the line one sees the same driving point impedance Zo in both directions and there are no discontinuities in Zo to cause reflectons, and so the reflection coefficient must be zero and (Zo - Zo)/(Zo + Zo) is the only formulation of a reflection factor that supports that condition.

I hope this "treatise" helps you to understand my thoughts on this.

Hi Ed,

Thanks for the info. I agree with you about BPL. It's a bad, bad idea.

My suggestion to you: double- or triple-check your postings for easy
stuff like typo's. It's especially bad when you say that "there was a
typo in the formula", and then your posting says:

========== [start quote] =============
The easiest wa to do that is to run a 3 D model
========== [end quote] =============

I know what you meant, of course, and so did 99% of the rest of us. But
the "competition" will use this against you.

This subject (BPL) will become huge, and you don't want people sniping
at you, implying that you can't spell, or whatever. That will detract
from the issue, and that is how some people accomplish their ends.

All the best, and 73,
Dave

[snip]

There is no reflection at a Zo-match!

There are no "waves", only particles, photons and electrons to be precise!

Waves are an illusion, the dynamics of electormagnetic radiation are explained fully by quantum wave mechanics, the electrodynamics of waves was replaced long ago, in the 1930's by QED, known as quantum electrodynamics. Einstein was the first to note and explain the strange inter-relationship between electrons and photons. He won a Nobel Prize for that piece of work. But poor Einstein could never reconcile quantum mechanics with his relativity theory. His biggest problem was that quantum theory predicts that quanta can communicate at speeds faster than the speed of light when they become entaangled.

Check out Feynman's Lectures for an "undergraduate" introduction to QED, and find out why "waves" are just plain WRONG!

There is an interesting book out in the bookstores recently, written for the layman, which details the strange life of quantum mechanics, the book is a great read:

Amir D. Aczel, "Entanglement", Four Walls Eight Windows, New York, 2001.
ISBN 1-56858-232-3.

Costs around $20 in hardcover. Includes lots of juicy details of the private lives of some of the main protagonists. e.g. Erwin Schrodinger was a "rake", etc... as well as a pretty good explanation of some of the things still to be resolved in quantum mechanics, I think you would enjoy.

They were MIT EE professors. I think Fano has written a more recent book on this. MIT is often considered to be the best engineering school in the US. (Keep forgetting you live "over there")

You are making me work my tail off trying to understand just what they did. You have a line of impedance Zo with load Zr at point z=0. Normalize, Zn=Zr/Zo. Since the angle of Zo is within +/- 45 degrees, the angle of Zn is within +/-135 degrees. He draws some vectors and decides maximum gamma is when the angle of Zn is +/-135. He solves for gamma^2, takes the square root, and ends up with gamma =

1 + SQRT(2)

I couldn't massage the numbers just right, but the decimal number I got suggest that max Gamma occurs when

Zo = k(1 - j1)
Zr = jkSQRT(2) k is the same k

He goes on to say that as you move away from z=0, the reflection coefficient becomes smaller by e**2alpha|z|

This is probably a never ending discussion, but I wanted to point out that these guys don't think there is anything wrong with your gamma of 1.8 ; especially since Slick brought it up again. I do not want to retake Fields & Waves

one more time and then i am transfering to a new computer and will probably lose my watch on this thread.

you have also hit on the basic problem in this discussion. there are two totally different topics in play here and they are getting mixed up back and forth all over this thread.

case 1: transmission line with a load.. this is the 'classical' case studied in ee classes world wide that yeilds the voltage or current reflection coeff of (Zo-Zl)/(Zo+Zl). the derivation is extremely simple and takes into account losses on the transmission line properly. a 'conjugate' match has nothing to do with this discussion, and nothing in the driving source is important to the calculations.

case 2: generator feeding a load... this is the other problem that has somehow been pulled into this thread and keeps getting mixed up with case 1 above. in this case we have a load impedance... however you may derive it, just as a lumped load or as a load at the end of a transmission line transformed back to the generator via the appropriate transmission line methods... this case is used to solve for maximum power transfer from the generator that has an internal impedance to the load impedance (note, this is the load impedance AS TRANSFORMED TO THE GENERATOR END OF THE LINE!). in this case you can solve for the maximum power tranfer and get your conjugate match condition, essentially where the generator and load have opposite reactances but the same real resistance. in one web site and apparently other books someone has defined another type of reflection coefficient that looks at this junction between the generator with its impedance and the load

impedance, this one apparently includes the conjugate of the load impedance in the numerator.

keep your conditions straight or these discussions will go on for ever with both sides knowing they are right and that the other one is wrong.... but only because they are discussing two different problems.

Who needs it? Of what use is it? Don't phasors contain all the important
information? What problem are you trying to solve by resorting to
instantaneous energy and/or power? You will never understand
instantaneous energy until you understand virtual photons. That's a
reasonable statement based on the latest quantum electrodynamics. Do
you understand virtual photons? Are you going to try to understand
virtual photons in order to really understand instantaneous energy?
If not, why not? Methinks you are the pot calling the kettle black.

The optics physicists have done just fine understanding everything while
dealing with irradiance (average power). Instantaneous power is simply
not a very useful concept except in some esoteric applications.

Okay, popped the lid.

One end of the roller inductor is grounded, as is the rolling tap. The
other end of the inductor connects to the variable capacitors. When
the counter registers "000", the rolling tap is at the end of the
inductor connected to the caps. This would be maximum inductance?

The EE Times August 25, 2003 cover article is "Smarter grid could warn
of impending blackouts". Leftari Tsoukalas of Purdue University (and
others) proposes smart monitors on the grid. The idea is to prevent
massive blackouts by better understanding and controlling the grid.
Good as far as it goes. However...

The article carefully does not mention how the information gets around
the grid. The implication appears to be BPL. E.g., they refer to
microcontrollers at the power meter (few of which have ethernet cables
and DSL connections as far as I know).

Is anyone in a position to actually find out what Purdue is up to?
And perhaps forward the BPL RFI concerns to them before this goes much
further?

Frankly, the article's timing looks amazingly similar to the energy
industy's "Gosh, 9/11, we'd better drill ANWR" opportunism.

Tam, I did not say your value of 1+Sqrt(2) was incorrect.

But when 3 guys you happen to have heard of say so, it hardly constitutes a proof. Why bother to mention them.

If you have any doubts about a particular matter the only way to understand what goes on is to work it out for yourself with pencil and paper. Otherwise you will remain dependent on mere acceptance of numbers found in books - if you can find a book. And has been re-discovered in these threads - books disagree with each other.

Good books teach you how to work things out for yourself from first principles. Then you can stop referring to authors. But these days so-called engineers are more inclined to misplace their blind faith in computer programs. ;o)

Yours, Reg, G4FGQ

>Why do you bring up bizillion volts? What is the conflict you see?

Hi Cecil,

It's obvious you didn't understand what you have been
saying for the last 6 months. What was said is what you have said, if
you "think that" then what is obvious is riddled with holes by your
own admission. Its shelf life is very limited too. :-)

The conflict? A bajillion is much less than a bizillion. That is why
you act like it is a far out big deal.

Hey, Reg, it's just a simple high-school (well, maybe first-year
college) differential calculus problem. Just let Garvin work through
it for us. Hey, good Dr., could you do that for us? Just write an
expression for |Vr/Vf| = |(Zl-Zo)/(Zl+Zo)| in terms of Rl and Xl and
find the partial derivatives with respect to those two variables, and
set both equal to zero, while letting Ro=Xo. It's mostly just a bunch
of bookkeeping. You should come up with values of Rl and Zl in terms
of Ro, and you can check to be sure that's actually a maximum and not
a minimum or saddle point. You should see a symmetry for Ro=-Xo, the
more usual limiting case.

Cheers,
Tom

Hi Cecil,

To date you haven't fielded many practical problems of "optics" as you
describe it. And the admission above is a poor excuse in place of
simple applications, never mind the esoteric ones you stumble over in
the dark bands.

A simple example which might offer you 50% chance of being right using
simple irradiance (average power, so average that their steady
illumination doesn't change during the entire time you ponder):

Which is brighter?
1.) 629 lux
2.) 5.0 millicandela/cmï¿½

Which is visible in sunlight? (mark with an "x")
1.) _
2.) _
Sunlight being defined as the irradiance observed beneath the
equatorial Sun on the equinox at local noon on a cloudless day.

"If" you got any multiple guess right, a tougher question that
involves more skill and relates to the source power for each:

What is the source total intensity for each value above with either
source at 10 centimeters remote? (either source being isotropic)
1.) _____
2.) _____
expressed in Lumens total flux (or make it simple on yourself, Watts
total radiation)?

Source record: 109475

If you cannot convince yourself to put in the pile of ground radials, you can use an ELEVATED 40 meter vertical. You can SHUNT FEED it so that it does not require an insulator, making the whole affair solid grounded to boot. Your radials should be a minimum of 9 feet up off the ground. You may make the shunt section out of six inch TV twin lead stand off mast clamp spacers, and use not much of a spacing for the trimmer capacitor for the gamma match that feeds it. You will find that you can take about a three foot section of RG-8 coax, and turn it into a capacitor by connecting the shield to one side of the coax feed line and the center conductor to the gamma match wire section which you make out of ordinary copper wire or whatever.

Put a couple turns of hard copper ac wire around a screwdriver handle. Put that across a common antenna insulator as a two turn coil. Connect that in series with an elevated radial. Stick a grid-dip oscillator in the middle of that little loop and tune the radials to reasonance by shortening them from too long to your target frequency. Adjust the length and the gamma match deal with an AEA or other antenna analysis unit for flat SWR at the coax feet terminal for your project.

Using the totally grounded method described lets you go down to the base of the pole and make SURE that it goes to a good ground rod. Use a few short six or eight foot radials at ground level to create the drain for any direct lightning hit you may take. The idea works very well from experience and more than one hit.

Run your coax feed line for the affair to the base as well and thence into the shack, using techniques that ground it well too, plus proper interface lightning suppression where the coax comes into the shack as well.

Here in the W5 call area, with a KW against it and a good receiver, on CW in either the CQ-WW or the ARRL CW DX test, I've consistently been able to pile up between 80 and 100 countries in any given contest .. often as many as 400-500 plus 40 meter QSO's. By using flag pole techniques you can make it look as neat as a pin for the inquisition .. grin.

If you have noise problems, you can help that with the new cancellation RF devices. As well, you can also design the thing so that you can cover 80 meters too!

The way to do that is to create the main vertical element so that it also has a folded loop operation all the way up to the top and down. On 80 you feed it is a folded monopole. On 40 you short that folded monopole at the base ,, a presto you have you full length 40 meter

element with a wider element profile, that is all.

Proper use of a Rohn 25-G few sections and a concrete ufer style base can get you a completely self-supporting element for the basic contruction. The neat part of this is that you can go inside that tower and run additional coax up it to get a small VHF antenna or dish up there. Or you can also side straddle mount a little Wireless 802.11 paddle or dish up there and PRESTO, if there is an IP wireless service, you can run that or whatever through, say, CAT-5 inside the tower .. and instant high speed connection for you as well. Just bring the internal lines down the inside of the tower and do the lightning mitigation work at the base for them as well.

Yes, you'll have to adjust the tower height to account for the effect of whatever other metal mass is up there for stunts like this, but you *CAN* do it and do very well on 40 and 80 too! Plus if you get bold. you can get a full sized 80 meter stick up there with Rohn 25-G and a galvanized mast stinger on top which works just as good on 80. But you'll have to use guy wires and so on for the elevated version, which of course has those longer elevated radials as well.

It's neat as a pin, terribly structurally efficient, and works a heck of a lot better than any horizontal affair you are likely to get up in your restricted space.

W5WQN ..

Hi David,

If you don't respond with an answer, I will mark it up to your having
lost track of the thread through your computer swapping. I quoted
only as much of your post to offer that I have no interest in the
conjugation issue whatever logic it is cloaked in. This is a simple,
practical example expressed in heat lost in the transmission line.
Very simple conditions, two resistors and a hank of transmission line.

The scenario begins:

"A 50-Ohm line is terminated with a load of 200+j0 ohms.
The normal attenuation of the line is 2.00 decibels.
What is the loss of the line?"

Having stated no more, the implication is that the source is matched
to the line (source Z = 50+j0 Ohms). This is a half step towards the
full blown implementation such that those who are comfortable to this
point (and is in fact common experience) will observe their answer and
this answer are:

"A = 1.27 + 2.00 = 3.27dB"

"This is the dissipation or heat loss...."

we then proceed:

"...the generator impedance is 100+0j ohms, and the line is 5.35
wavelengths long."

Cliff,

M2, HyGain, and at least one CushCraft use the 4:1 balun that consists of a 1/2 wave section of coax on some beams. Gets kind of long below 10 meters, but no reason it wouldn't work with a folded dipole. You would end up with about 70 Ohms.

Most hams use a 4:1 balun with a folded dipole instead of the more
complicated 6:1 balun. "300 ohm" window line usually has a Z0 less
than 300 ohms. The stuff I have is about 275 ohms.

Hehe...Whose the bully now, Roy?

It very simple Roy, and no complex math is needed to understand
it. The port impedance does not change from when the incident power
is launched and when the reflected power returns, so the power will be
((Vrms)**2)/Zo). So if the RMS voltage returning is greater that the
power you put in, you MUST have an active device.

If you simply square the MAGNITUDE of the voltage reflection
ratio, you will get the power reflection ratio. So if the voltage RC
is greater than one, so will be the power reflection coefficient.

This is so basic, Roy, that i don't see how someone who I had
admired before cannot understand it! And please understand that i
didn't invent the conjugate equation, it has been there all along.
Reg just convinced me that the "normal" R. C. equation must be wrong
for complex Zo. And he is correct.

Please look it up in any basic RF book: For a passive network,
0=<rho=<1. But the R. C. can never be more than one for a passive
network.

[snip]

We too have a Nova Scotia place [a condo] on the Halifax waterfront but I
don't have
any antennas up there yet either. I hope to have antennas up in both
places, i.e. Indialantic
and Halifax probably later in the New Year.

My current radio hobby project, fitting it in between consulting jobs. I'm
supposed to be fully
retired but find that I am only semi-retired :-). is to outfit my Expedition
with an IC-706 and a
Tarheels screwdriver both of which I bought just after Dayton. But I
haven't even drilled holes
in the Expedition yet.

Procrastination is ruining my hobby!

I've never been HF mobile, wanted to try that.

I was thinking I might like to try some DXpeditioning now that I am supposed
to have the time.

Sigh.

[snip]

No, I can't keep them separate, because essentially they are the same!

Consider a transmission line of surge impedance Zo(w) = Zo(w) where Zo(w) is
in general complex:

Zo(w) = sqrt[(R + jwL)/(G + jwC)] where

R, L, C and G are the traditional distributed primary parameters.

Now consider that it is possible to synthesize Zo(w) as an ordinary impedance, instead of a
surge impedance, as closely as desired.

Now design a generator [Thevenin Equivalent for example] with constant voltage source
of voltage "2a" Volts RMS, behind that impedance of Zo(w) you just synthesized. I use
the symbol "a" in the generator voltage simply because the generator voltage *is* the incident
voltage, it is actually twice the incident voltage, but in fact is the cause or prime mover for
the incident or forward voltage on the line, and so I call it what it is "2a". The generator
voltage is really just a scaled version of the incident voltage on the line.

Connect that generator of "internal" impedance Zo(w) to a semi-infinite chunk of that transmission
line of impedance Zo(w), so that Zo(w) becomes "the load Zl" on that generator and you have an
image match between the generator and its' load. You now have the semi-infinite line terminated
in its' own surge impedance Zo(w).

At the connection of this generator and load [which just happens to be a semi-infinite transmission line
of surge impedance Zo(w)] the incident voltage wave consists of "a" Volts RMS across the line and
b = 0 Volts RMS of reflected voltage across the line.

"The reflection coefficient" at the generator and the input to the line is then the ratio of the reflected
voltage b to the incident voltage a, rho = b/a. In this case rho = (Zo - Zo)/(Zo + Zo) = 0
[in both directions!] and the reflected voltage on the line is b = 0. I use "a" and "b" because those
are the symbols usually used in the Scattering Matrix formulation and they are a lot simpler to
type than the usual Vfwd and Vref, for forward and reflected voltage, etc... Don't you agree
that "a" is a better symbol than "Vfwd" and "b" is a better symbol than "Vref"?

Note that the open circuit voltage of the generator is "2a" Volts RMS and is just twice the incident
[forward] voltage at the end of the line. Actually the 2a volts is the cause or prime mover for the
incident voltage at the line's terminals.

And so... I assert that the connection of a generator of impedance Zo to a load of impedance Zo is
indistinguishable from the connection of two semi-infinite lines of surge impedance Zo.

Is this not right? All the currents and voltages and waves are the same.

This is an "image match".

Now to see the difference between an image match and a conjugate match, just change the generator impedance
from Zo to the conjugate of Zo. i.e. if Zo = r + jx, just make the generator impedance conj(Zo) = r -jx. Then leave everything else the same and recompute rho and b.

These two scenarios both of which entail the connection of a generator to a load, one image matched to the load and the other conjugate matched to the load, with the load being a semi-infinite line of surge impedance Zo, ties up the whole discussion in one neat little package, no?

And there are not two separate cases as you suggest, one being generator impedance matching and the other being transmission line interconnections.

Generator impedance matching and transmission line interconnections are identical situations, having all the same variables i, v, a, b, etc... you can look at reflection problems in either scenario, transmission lines or generators and loads. The calculations and formulas you use are all the same. They are not different as you suggest.

Thoughts, comments?

> 73, Cecil http://www.qsl.net/w5dxp
[snip]

In a nutshell, photons do not cancel. :-)

According to the [strange and un-intuitive] quantum electrodynamics theory a photon can literally be in two places at once. i.e. if you send a photon towards two slits in a wall, it will pass through both slits simultaneously, and interfere with itself, but if you put a photon counter at the slits, on either side, you will count only one photon.

Nobody's intuition works for QED!

To get engineering answers, you just have to "crank" the mathematics, or manipulate Feynman's little diagrams, and find out what happens.

Apparently there is no "why" and no good analogies for photon/electron interactions to situations in our "normal" world.

And QED is now accepted by all of modern science and forms the basis of all electrodynamics and is indeed the phenomena behind the waves we all discuss here on rraa!

Indeed when you resolve or magnify the aggregate wave models we discuss here on rraa down into their constituent photons, QED is what you get!

QED underlies and superceeds all wave mechanical theories. And waves are replaced by probabilities.

Waves are an illusion, they are not the way Mother Nature works!

Deal with it!

If anyone is interested in really getting to the bottom of this endless jousting, turn to page 136 of "Theory and Problems of Transmission Lines" by Robert A. Chipman. This is a Schaum's Outline book - mine is dated 1968. Many professionals acknowledge that this is one of the most succinct and revealing accounts of t-line theory to be found. Mathematical enough to be rigorous but readable and highly useful.

Starting in Section 7.6, Chipman derives the full set of equations for lines with complex characteristic impedance. I will make no effort here to repeat the development with ASCII non-equation symbols, but the bottom line is that in the general case, Zo is indeed a complex number which can be highly frequency-dependent.

Under the condition of certain combinations of physical parameters of the line, Zo does indeed become actually real - the so-called Heaviside Line where R/L=G/C where the symbols have the usual meanings - and independent of frequency. This is the only case wherein a lossy line can have a real Zo.

Finally, he clearly shows how terminating an actual physical line appropriately can result in a reflection coefficient as large as 2.41.

This revelation DOES NOT imply that the reflected wave would bear more power than the incident wave. For a line to display this behavior, it must first of all have a high attenuation per wavelength. Due to this high attenuation, the power in the reflected wave is high for only a short distance from the termination.

A couple of surprising consequences of this:

1. in order to terminate a line with complex Zo such that rho is greater than 1, the reactance of the load must be equal and opposite to the reactive term of Zo. In other words, the line and the load form a resonant circuit separated from "the rest of the system" by the very lossy line.

2. calculation of the power at any point on a line with real Zo, lossy or not, is simply Pf - Pr. But for a complex Zo, this is no longer true and a much more complex set of equations - given by Chipman - must be used. See his equations 7.34 and 7.35.

Finally, it should be understood that these effects are found almost entirely on low-frequency transmission lines. Dealing with complex Zo is routine with audio/telephone cable circuits and the like.

At HF, the reactive component of Zo for most common lines is so small as to be safely and conveniently neglected. For example, RG-213 at 14 MHz has a Zo of 50-j0.315 ohms. The same line at 1000 Hz has a Zo of 50-j35.733 ohms. (Values taken from the TLDetails program)

When terminated in 50+j0 ohms, the SWR on the line is 2.012.
When terminated in 50-j35.733 ohms, the SWR is 1:1 as would be expected. But when terminated in 50+j35.733 ohms, the SWR is a whopping 5.985.

RG-213 is nowhere near lossy enough to display the resonant-load effects Chipman discusses, but these data give some idea of the perhaps unexpected consequences of using even a common line like RG-213 at a low frequency.

Taken to 100 Hz, we find Zo = 50 - j 113.969 ohms and when terminated in 50 + j 112.969, rho is determined to be 2.25839. Note that the termination is a passive circuit in all these examples.

I urge anyone seriously interested in understanding transmission line theory to include Chipman on their bookshelf. Despite its assumed low station as a Schaum's Outline book, it provides a source of information and understanding seldom matched by any text.

Hi George,

I have notice you recommended this author several times, and yet you
have casually dismissed his rather straightforward coverage relating
to the characteristic Z of a Transmitter:
>> There is no need to know, since its value, whatever it might be, plays no
>>role in the design and implementation of the external portion of the system
>>driven by the transmitter.

How do you reconcile this with his coverage entitled
"9.10. Return loss, reflection loss, and transmission loss."

You may wish to observe the clearly marked figure 9-26 and
specifically the paragraph that follows (or the entire section for
that matter) that quite clearly reveals what is everywhere else
implied: that ALL SWR discussion presumes a Zc matched source. You
may observe that Chapman thus refutes your statement above. Further,
Chapman goes to some length to describe the Smith Chart's appended
line evaluation scales at the bottom to this very matter.

To substantiate this from other sources I have offered a very simple
example that shows this importance that to date has defied "first
principle" analysis (not first principles however, merely the claim of
its being practiced analytically in this regard). I will offer it
again, lest you missed it.

The scenario begins:

"A 50-Ohm line is terminated with a load of 200+j0 ohms.
The normal attenuation of the line is 2.00 decibels.
What is the loss of the line?"

Having stated no more, the implication is that the source is matched
to the line (source Z = 50+j0 Ohms). This is a half step towards the
full blown implementation such that those who are comfortable to this
point (and is in fact common experience) will observe their answer and
this answer are:

"A = 1.27 + 2.00 = 3.27dB"

"This is the dissipation or heat loss...."

we then proceed:

"...the generator impedance is 100+0j ohms, and the line is 5.35 wavelengths long."

Beware, this stumper has so challenged the elite that I have found it dismissed through obvious embarrassment of either lacking the means to compute it, or the ability to simply set it up and measure it. It takes two resistors and a hank of transmission line, or what has been described by one correspondent as:
>>There is no institutionalized ignorance, just a
>>lot of skepticism regarding the reliability of the
>>analysis methods and the measurement methods.
Clearly a low regard for many correspondent's abilities here, and hardly a prejudice original to me. Imagine the incapacity of so many to measure relative power loss - a CFA salesman's dream population.

Actually it is quite obvious several recognize that follow-through would dismantle some cherished fantasies. Chapman clearly knocks the underpinnings from beneath them without any further effort on my part. But then, as you offer, they would merely dismiss it by confirming another prejudice:
>its assumed low station as a Schaum's Outline book

I would point out to all, that Chapman's material dovetails with what would have been then current research and teachings of the National Bureau of Standards. Prejudice has "refuted" those findings too. :-)

The terminated line I'm comfortable with. "Semi-infinite" isn't in my
lexicon, but I'll see where it goes.

Maybe the trouble is with the "semi-infinite" aspect, but here we part
company again. The termination at the source end of the line is, by
definition, the source impedance, which is zero, not Z0.

Can't you do this analysis with a plain, ordinary, transmission line of
finite length? Lossless is ok, lossy is ok. Or is your proof true only
if the line is "semi-infinite" in length (whatever that is)?

The old Heathkit dual coil setup is what you are talking about.
They were not single band but could be used with any 300ohm
fed folded dipole on any of the 80 - 10 bands in use at that time.

Unfortunately, probably due to my poor description, you have missed
the point I was trying to make.

You are, I think, disagreeing with the RESULT of step 7.

Even though the result may be wrong, step 7) can be correct.

Step 7) again:
"7) From 6), the energy crossing quarter wave points is 0"

This is saying that if the result of step 6) is correct, then
the result of step 7) is correct. The transformation from 6)
to 7) merely integrated power to get energy; a common and
correct thing to do.

So if you disagree with the result of step 7), it is in step 6)
which you must search for the error since step 7) is correct.

If step 6) is correct, then search in step 2) and step 5) for
the error.

I suspect that like Cecil, you will end up at step 2) as the
source of what you perceive to be an error.

Then, when we resolve whether 2) is in error, we will know
whether the result of 7) is in error.

I've being using p(t) = v(t) * i(t) and simply arguing that when
v(t) or i(t) is zero for all t, then there is no power.

Poynting won't change a thing. There is no P when E or H is zero.

So the debate can be had with the simpler p(t) = v(t) * i(t).
There is no need to complexify.

I do like pulses. Thinking about pulses on the line certainly helped
clarify my understanding of how lines worked.

So what happens when two pulses collide? I don't think you will like
this answer either, but here goes.

First, remember that power and energy are not the same. Power can
become zero while the energy remains. It simply means that the
energy is now stored in the capacitance or inductance (or equally,
the E field or H field) but is not moving. So no energy is lost
or destroyed when the power goes to zero.

So what happens to these two pulses? They bounce off of each other
and return whence they came. This must happen since the voltage on
the region of the line where the two pulses collide remains zero
and since p(t) = v(t) * i(t) there is no power in this region
so there must be no energy flowing. You would observe exactly
the same result were you to short the line at the point of
collision just before the collision occurred. Two pulses colliding
is just like a reflection.

As a simple analogue, consider two identical elastic balls rolling
towards each other. They bounce back after the collision.

On a line this is easier to visualize with two negative pulses
colliding. Each pulse consists of a clump of charge. When these

clumps of charge collide, remembering that like charge repels, they bounce back.

What actually happens during the collision? With balls, the energy is stored in the deformation of the ball and then released as the balls separate. With pulses, the power stops (current is zero), and the energy is stored in the capacitance of the line in the region of the collision. After all the energy has stopped flowing (no power, zero current, all energy in the E field), the energy is released into the reflected pulses and once again, there is energy moving (power) on the line.

Note that waves can pass through two slits at the same time. :-)

A footnote from _Optics_: "... although the light-is-corpuscular model has wide acceptance ... and is a crucial part of the contemporary discourse, like almost everything else in physics, it is not yet established beyond all doubt. See, for example, the summary article by R. Kidd, J. Ardini, and A. Anton, "Evolution of the modern photon", Am. J. Phys. 57 (1), 27 (1989)."

> Deal with it!

Accept on faith the existence of God and virtual photons? :-)
To me, God and virtual photons seem to both be band aids for things not yet understood by man. To me, the following two statements don't seem all that different.

1. Although completely undetectable, virtual photons have to be the vehicle by which electrons communicate their presence to each other.

2. Although completely undetectable, God has to be the vehicle by which everything was created.

It just occurred to me that virtual photons might explain telepathy. What do you think?

Very interesting subject. It's sort of like getting new eye glasses. You don't realize how bad the old glasses were until you get new glasses. With regards to antennas we had the tin (steel) roof on our home replaced with a normal roof. After a few months I have come the conclusion my antenna system is working much better now. It was like getting a new antenna. I had no idea the steel roof was effecting the antenna performance. The SWR is the same but the 3 elment beam seems to work better with the new roof.

There is no doubt that energy moves. The point of disagreement is on
how far it moves.

This last is true, but p(t) = v(t) * i(t); volts and amps must be
present simultaneously for there to be power.

There are many assumptions in this discussion which means it only
applies
to ideal lines. The extension to real lines, retains the fundamentals
but the details need tuning.

As a simple example, on a real line, the nulls are never 0.
But including this in the discussion would just make it more difficult
to locate the points of disagreement.

> Keith wrote:
> "Try visualizing how a step function charges the line."

Understanding a step will help with understanding line
behaviour. This knowledge can then assist in understanding
sinusoidal steady state.

Of course, there are the two component Poynting vectors which each
contain power. How else could (Pz-/Pz+) = |rho|^2

You are continuing to confuse NET power with component power. The
NET Poynting vector is zero. The component Poynting vectors are
Pz- and Pz+ and NOT zero as explained in Ramo & Whinnery. The sum
of the two Poynting vectors is zero at certain points because they
are 180 degrees out of phase at those points. 1/4WL away, they are
in phase.

So when I use my voltmeter to measure a voltage, I actually have
two voltages present which sum to the reading.

When I do this on a D-cell, what are these two voltages?
When I read 0 on a piece of NMD-90, what are these two voltages?
When I read 0 on D-cell, what are these two voltages?
When I read 120 volts on a power outlet, what are these two voltages?
For each of the above, explain how you decided.

It would seem that this belief will lead to some serious decidability
issues.

And don't ever trust your voltmeter again.

Looks like you are never going to understand the principles of
superposition and interference until you read and understand
those chapters in _Optics_ or similar reference. You continue
to make the same mistakes over and over in spite of the obvious
mental violations of the principles of physics which have been
explained to you.

Yes, that's why you need a directional voltmeter or directional
wattmeter to separate the forward wave from the reflected wave
when reflections exist.

> When I do this on a D-cell, what are these two voltages?

Reflected voltage is zero during DC steady-state.

> It would seem that this belief will lead to some serious decidability
> issues.

If standing waves exist, there is one forward wave component and one
reflected wave component. If standing waves do not exist, there is
no reflected wave component. Shirley, you can tell whether standing
waves exist or not so you will know whether you are dealing with one
or two waves.

> And don't ever trust your voltmeter again.

Do you use a DC voltmeter to measure AC? Do you use a 60HZ AC voltmeter
to measure 1 GHz RF voltages? Do you use a 100MHz o'scope to look at
a light wave?

If reflections exist and you are using a non-directional voltmeter, you
will read the NET voltage. USE THE APPROPRIATE MEASURING INSTRUMENTS!

Keith wrote:
"I suspect that like Cecil, you will end up at step 2) as the source of what you perceive to be an error."

Where ever the error first appears, it is obvious that "-the energy crossing quarter wave points is 0", is wrong.

Energy flow in a usual shortwave transmission line is continuous. You feed continuous sinewaves in and get continuous sinewaves out, no interruptions created by quarterwave point manifestations of standing wave zeros. Standing wave zeros don`t equal power stoppages. These zeros have zero effect on energy flow.

Proof is that a directional sensor finds the same power flow, forward or reflected, at a standing wave zero point as it does at a standing wave maximum, or at any point in between.

Power is joules per second (watts). A joule is the energy required to transport 1 coulomb between two points having a potential difference of 1 volt. So, if power crosses a point, energy crosses because it is a part of the power (the rate of doing work).

Best regards, Richard Harrison, KB5WZI

But how did you know this little cylinder with a bump on the
end produced DC? And why can't DC circuits have net voltages
derived from superposition? Seems that in your model you need
extra information before you know what your voltmeter is telling you.

I observe that you did not provide an answer for the other examples.

What about that power plug on the wall? Too difficult?

Feel free to assume that you own an abstract voltmeter which will
tell you the voltage as a function of time (an oscilloscope maybe?).

Since we are discussing the world of the ideal, we can assume the
existence of ideal voltmeters.

> If reflections exist and you are using a non-directional voltmeter, you
> will read the NET voltage. USE THE APPROPRIATE MEASURING INSTRUMENTS!

So I will rephrase my question for your benefit:

When we measure a voltage using an ideal voltmeter, how do we know if this voltage is composed of components (I generalize, since similar difficulties arise in situations without reflections) so that we can do extra measurements and computations to learn the 'real' voltages and 'powers'?

If you wish, the wall outlet provides an excellent opportunity for explanation by example.

You don't!
It is this way: If You put up the antenna high enough, You might hear
A, B and C. However, You might not hear X,Y and/or Z, or at least
have very poor reception, as the radiating angle is to low for short
skip.
X,Y and/or Z might end up in the "skip zone". If You LOWER the antenna,
the semi-locals turn up, but You lose A,B and C.
So Your dipole CAN not pick up everything simultaneously.

understanding of how lines work."

Time domain, frequency domain, its all the same.

If you have a distortionless line, that George, W5YR calls a "Heaviside Line", or if you have a lossless line of wide response and equal velocity for all frequencies, your pulse can remain undistorted. The pulse is then just a fundamental and a bunch of odd-harmonic frequencies.

Waves of single or multiple frequencies travel in opposite directions on a line transparently right through each other with no lingering effect upon each other. Waves don`t bounce off each other. They only bounce off impedance discontinuities.

Best regards, Richard Harrison, KB5WZI

Your use of the term complex math is appropriate in that V+, V-, and gamma
are all complex numbers. For the case of gamma = 2.41, its phase angle is
about 65 degrees, and the *real part* of gamma is 1.0.

In the ARRL antenna book, in the chapter on portable antennas, there is an article on a folded dipole using 300 ohm tv twinlead, which is matched using a capacitor, or a stub of 300 ohm twinlead.

I've had one of these for 80 meters for over two years, and I'm quite happy with it. I made it with "rat shack" TV twinlead, exactly according to the cookbook, and it has a 1:1 SWR right at 3775. My rig has no problem matching across the entire band, and the SWR around 3510 or 3990 is just approaching 3:1.

I chose to use the stub match, because I had the twinlead handy. Dressing the stub away from the feed line is the biggest drawback I found.

Its mounted as a shallow vee, with the apex at about 50 feet, ends at about 30 feet.

Just a different method of matching, but its simple and functional.

Keith wrote:
"When we measure a voltage using an ideal voltmeter, how do we know if the voltage is composed of components---?"

Keith earlier gave an answer, the oscilloscope is appropriate for voltage composed of differing frequencies. But, for a voltage composed of same-frequency components, something more exotic is required to fit the situation, such as a directional coupler in addition to the scope or other meter.

Where a composite voltage of various frequencies exists, there are frequency-selective voltmeters to quantify individual components. The loading these components impose on a common system is based on the probability of their peaks coinciding.

> extra information before you know what your voltmeter is telling you.

The extra information is that you are dealing with an RF transmission line with reflections. The reflections are somewhat equivalent to a second source. And in a two-source DC circuit, you can indeed have net voltages derived from superposition of the two source voltages. Put them in series adding and you get a voltage maximum. Put them in series subtracting and you get a voltage minimum.

> What about that power plug on the wall? Too difficult?

Too many sources, too many feedlines, too many loads. And the wavelength is really too long to illustrate RF transmission lines. I get a wavelength just over 3000 miles, which would stretch out straight from Texas to Alaska.

> When we measure a voltage using an ideal voltmeter, how do we know if
> this voltage is composed of components ...

For an RF transmission line, use a directional wattmeter to ascertain if reflected power exists. If your 50 ohm SWR meter is in a 50 ohm Z0 environment, it will indicate the presence or absence of reflected power.

> If you wish, the wall outlet provides an excellent opportunity for
> explanation by example.

Nope, it doesn't. That wall outlet doesn't have one source, one feedline, and one load. If you had one 60 Hz generator hooked up to 3100 miles of lossless transmission line, you could certainly observe reflections over that one wavelength of wire.

Hi Tam,

It is the second reference and it is found on page 8. No doubt those
authors also understand that source characteristic Z must be equal to
transmission line Z to characterize SWR on the line. Of course, at
this point I cannot vouchsafe for that specifically, however, it seems
unlikely anyone here will negate the premise.
Except to say "t'ain't so." ;-)

I said "at this point" as this could be resolved (or from the other 11
references) by my visiting my engineering library at the U. This will
not prohibit others from denial however which simply mocks Chapman's
work and those he references.

I won't put the challenge I have offered others to you. You probably
would have answered it by now if you could have.

Terry, If you use the MFJ 259B version you can go to Advanced Mode by depressing 'Gate' and 'Mode' simultaneously. Press the 'Mode' switch to cycle through the options. Select 'Resonance' Mode. You now can sweep across your system, starting at the lowest frequency range [1.8 MHz] and determine resonance at the Zero reactance frequency. Be advised, that the load may not be 50 ohms though!!

If you plan to be at your QTH for a while, it's not difficult to
lay untuned radials along the ground, or bury them down a half inch
or so with a pizza cutter. I laid mine in the grass and after a
couple of months you don't even see them anymore -- the mower goes
right over them. If you are concerned, you can nail them down
using hairpins. They not only serve as a great base for a vertical,
but they also provide a very good rf ground. They don't have to be
any special length -- its the quantity that counts.

4394. Ground system for a vertical antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-28 16:13:30 UTC
From: "David J. Windisch" <davidw@copper.net>
Message-ID: <3f4cd8c0_1@newsfeed>
Source record: 109438

Hi, all concerned:

The good news:

I picked up all the branches and twigs this spring, cut the grass short, and laid over 100 #14-insulated radials in a 150-ft-od circle on top of the cuttings. Stripped the wires at the center and used several split-bolts to tie all the wires into groups, and the groups of wires together and to the ground rod. Who sez you need a circular plate and all those bolts?

Ignored disapproving stares and didn't mow til the zoning guy sent me a letter. Still didn't mow. Weed-whacked "Radial Patch" into what the z-g said was compliance: 10 inches or less. Left the cuttings as they fell. Thought about redoing Radial Patch as Wildflower Patch, and bought some still-unplanted w-f seeds. Thought about various "edge" or "barrier" treatments suggested by z-g as "acceptable". Laid down pronto and those thoughts went away.

Waited til things got close to outta hand again. W-w'ed the outstandingly-tall clumps a bit, all 97 gazillion of 'em.

Sharpened (with hand-grinder from Harbor Freight: cheep cheep worky worky doesn't that sound odd when you say it?), balanced the mower blades and bent 'em (it ain't easy cuz they're either hardened or spring steel) so they curve up to around an inch higher at the ends, than in the centers. Fiddled with the mower-deck up-down cable adjustment so it really does pull the deck up as high as it goes.

Around the 15th inst., began to mow Radial Patch verrrry gingerly. Threw caution to the winds since no tangles after a few turns around May Pole, my 38-ft vertical, and accelerated to normal TimTheToolMan speed. Musta looked like a bobble-head, bouncing over all those duck-plucking mole mounds. Gotta find my old mouth-protector from my days as a footbal pretender. Might not bite my tongue or chip a tooth next time.

Still gotta staple a few visible short lengths down. Might cover 'em with topsoil.

Looks like I have a 2-pitcher lawn again, 3 if I work slow or drink faster.

Gotta enlarge that stupid small thing on the mower fender which masquerades as a beverage-holder.

The bad news:

Man!!!! are verticals ever susceptible to all the neighborhood noise I simply don't hear on my dipoles in trees! Oh, well, xmit on the verticals and receive on the horizontals. Or what? The verticals were quieter after

the power co had the trees trimmed lasty summer, but not lately, it seems. Funny how one gets used to noisy antennas and forgetshow quiet things can be.

Btw, it's only me and two cats. The only honey-do's I hear are "DX", and NIMBY. Ask me about the counterpoise mostly under the rug in the (former) dining room.

Fwiw.

TIA for reading. It's been a good summer "sabbatical", and I'm looking forward to doing real work again in September.

73, Dave, N3HE

Hi Cecil,

From Chapman (you following this George?) page 28:

"It is reasonable to ask at this point how, for the circuit of
Fig. 3-1(b), page 18, on which the above analysis is based, there
can be voltage and current waves traveling in both directions on
the transmission line when there is only a single signal source.
The answer lies in the phenomenon of reflection, which is very
familiar in the case of light waves, sound waves, and water waves.
Whenever traveling waves of any of these kinds meet an obstacle,
i.e. encounter a discontinuous change from the medium in which
they have been traveling, they are partially or totally
reflected."
...
"The reflected voltage and current waves will travel back along
the line to the point z=0, and in general will be partially
re-reflected there, depending on the boundary conditions
established by the source impedance Zs. The detailed analysis of
the resulting infinite series of multiple reflections is given in
Chapter 8."

The Challenge that I have offered more than several here embody such
topics and evidence the exact relations portrayed by Chapman (and
others already cited, and more not). The Challenge, of course, dashes
many dearly held prejudices of the Transmitter "not" having a
characteristic source Z of 50 Ohms. Chapman also clearly reveals that
this characteristic Z is of importance - only to those interested in
accuracy.

Those hopes having been dashed is much evidenced by the paucity of
comment here; and displayed elsewhere where babble is most abundant in
response to lesser dialog (for the sake of enlightening lurkers no
less). Clearly those correspondents hold to the adage to choose
fights you can win. I would add so do I! The quality of battle is
measured in the stature of the corpses littering the field. :-)

So, Cecil (George, Peter, et alii), do you have an answer? Care to take a measure at the bench? As Chapman offers, "just like optics." Shirley a man of your erudition can cope with the physical proof of your statements. ;-)

The only thing you and others stand to lose is not being able to replicate decades old work. Two resistors and a hank of line is a monumental challenge.

My office is located in a metal warehouse type structure which effectively shields us from most outside signals. If I want to listen to the radio or use my cell phone inside the building I have to open a bay door. Is there a way I can get all those radio waves inside the building without opening the doors. Is it possible to place an antenna outside and have everything rebroadcast inside? The main reason for this approach is the cell phone. It would be kind of impractical to run an antenna from my cell phone to the outdoors.

Barring the rebroadcasting idea, I am still interested in what the best way is to get better reception on the radio. Do I need to run a wire outside or somehow ground the radio. Go easy on me, I've heard some stuff about 7mhz being 23 feet long at a quarter wave. If your gonna spring some of that stuff on me I need a little more detailed information. I'm not up on radio lingo but I am technically capable.

TIA
The Bad Priest

While it may not work for you , look up "passive repeater" This is an antenna aimed at the desired station (on the outside of the building in your case) and a feedline inside the building hooked to another antenna.

For receiving other frequencies you may have to run a wire outside the building and either hook it to the receiver or wrap it around the receiver.

I have not seen it but have heard that in long tunnels they have an outside antenna and an amplifier and some inside antennas for the FM radio stations.

Richard's statement about what the directional sensor "finds" is perfectly correct - but unfortunately it cannot be used as proof.

The reason is that so-called "directional wattmeters" don't physically sense directional power flow. All they sense from the transmission line are the current and the voltage, as two separate samples. Then they add or subtract these samples to give the sensor its directional properties. All the meter reads is a detected RF *voltage*, which changes to a different value when the sensor is reversed.

If you want to know what those meter readings mean, you need transmission-line theory in order to understand them. You can then calibrate the meter to read forward and reverse power - but you cannot do that without using transmission-line theory to do it, and that theory is the subject of this entire discussion.

Therefore the readings of a "directional wattmeter" cannot be used as evidence for either side, because that argument would be circular - you cannot use any theory to prove itself!

However, this attempt to use inadmissible evidence doesn't necessarily affect Richard's wider argument about power flow. If that argument is correct, there definitely *will* be other physical evidence to prove it.

Years ago, I had a discussion with Jeff, WA6AHL, here on this newsgroup. I suggested that the impedance looking back into the source might be Vsource/Isource, i.e. the transformed dynamic load line. However, I have never taken a strong stand on source impedance. If reflections are blocked from being incident upon the source, as they are in most Z0-matched systems, the source impedance doesn't matter since there exists nothing to reflect from the source impedance.

My basic approach is to achieve a Z0-match and therefore forget about source impedance.

Unless the coax is very low loss, I'd have to put my money on the 300
ohm twinlead setup having the least overall loss, even counting the
little balun you will need. At least when dry... Or at least thats
what I found when I ran a large UHF TV antenna for 420 mhz ATV. I had
the least loss with the twinlead. MK

(Of course, that's not quite right, as I'm sure the good Dr. and Reg
both know. Since we're talking passive here, you need to insure that
Rl stays positive, so you just may need to check along the boundary
where Rl=0. And you should convince yourself that the most reactive
possible line really does yield the largest possible |Vr/Vf|. So it
becomes a task of finding the maximum value of a function f(Rl, Xl,
Xo) with Ro fixed positive non-zero, under the constraints that Rl>=0
and |Xo|<=Ro.)

The passive repeater is an excellent idea. I have done that extensively at Radio Shack. We had a TV antenna outside for the TV signals. We would be sure to run a feed-line to the inside TV demo antenna, and to a automobile antenna in the "car sound" display. We could then give relatively accurate demonstrations of the small transistor radios and auto stereos. You wouldn't believe it, or won't believe it until you try it. Two antennas connected by as sort a feed-line as possible.

Hi Cecil,

That's all fine and well. It exhibits a rather standard behavior and confirms conventional expectations. I take by this response that you have no interest in the confirmation of interference in both Optical and RF metaphors being visited at the bench. That is fine too. It is a rather tough example to replicate - except when stumbled upon, then we hear cries for exorcism being needed (my cue).

My missives simply offer touchstones of clarity in contrast to the murky sea of un-fettered statements. We are presented with fantastic notions that the characteristic source Z of a transmitter is unknowable, and this statement is usually closely allied to the notion that this same "unknowable" Z is actually responsible for reflecting all power arriving at the antenna terminal. Few of those who utter these witless jokes have any response to the straight line "So what is this Z that does all that reflecting?" In their chagrin, they fail even to repeat "it is unknowable...." Absolutely none can venture a guess that it is either: "much less than 50 Ohms," or it is "much more than 50 Ohms." This would be two obvious rejoinders and yet neither is uttered. Such is faith. The universal silence condemns their specious claims absolutely.

These absurd notions deserve a hearty laugh, because it invalidates the need for a tuner which is purposely inserted between the source and load to serve that very purpose (and which you describe as your typical habit which is a nearly universal application).

But, again, this discussion is generally reserved only for those interested in accuracy. :-)

Hi Cecil,

This is a cavalier attitude if you can afford it. Otherwise, those who so desperately hammer out the last 0.1 dB antenna gain are going to fall to their knees in wrack when they discover that their rig's characteristic Z of, say, 70 Ohms meeting the discontinuity of their low pass filter's 50 Ohms turns that effort into heat behind the antenna jack.

I have long since stopped being surprised by those who spin on like whirling dervishes over trivial matters in the face of 10 fold losses in front of them. This, of course, is even more trivial when they gush on about their premium equipment that behind the knobs "efficiently" transforms 20 - 25 Amperes of DC current into 100 Watts RF. Now, that puts perspective to the topic: smoke and reflection coefficient.

Garvin, it's a book, not a paper. Your bookstore can probably help
you with it. Besser, at least, apparently came to understand the
error of his ways on this point, and Besser Associates is now
presenting the correct formula in their classes, per the email I
posted from them. I haven't checked with Pozar or Kurokawa, but
strongly suspect you are taking their works out of context and
misinterpreting them.

Cheers,
Tom

Like I say, my solution is to block any reflections from being incident upon the source. But I have a question. Since we are discussing coherent sine waves, it seems to me that any reflection from the source impedance will become indistinguishable from the generated wave. In fact, the present convention of generated power equals forward power minus reflected power is designed to overcome that very problem.

Tom, to save everybody a lot of trouble -

The greatest theoretical value of the magnitude of the reflection coefficient occurs when the angle of Zo is -45 degrees, and the terminating impedance is a pure inductive reactance of |Zo| ohms.

Do you think I should have mentioned this when I began this and other threads by saying a reflection coefficient greater than unity can occur?

The riot police can now return to barracks.

Reg, G4FGQ.

The biggest clue that I have noticed is that nobody has been able to
generate standing waves in a single source, single feedline, single
load system without the existence of a reflected wave.

Hi Cecil,

So you DO want to perform this test?

Your presumption of coherency is false unless you engineer the
solution.

I got there first and made sure that wasn't gonna happen. :-)

Any random attempt has only a one in 360 chance of being correct
within one degree of coherent. This is simple interference math after
all. Most individuals would just notice a 10 degree error which would
boost your chances to slightly less than 3% - not very good coherency
wise.

Thank you for the detailed quotation - it explains just how you have
misinterpreted it.

When Chipman says:

>"The reflected voltage and current waves will travel back along
> the line to the point z=0, and in general will be partially
> re-reflected there, depending on the boundary conditions
> established by the source impedance Zs.

all he means by "in general" is that if the source impedance is not
exactly the same as the Zo of the line, there will be a re-reflection
and a new "second-generation" forward wave will start.

That's fine, because the second-generation forward wave will encounter
exactly the same conditions down the line as the first-generation wave
did. And when it is (partially) reflected at the termination and returns

to the source, a second re-reflection will spawn a third-generation forward wave... which will encounter the same conditions yet again. And so it goes on, in an infinite series of partial reflections at both ends of the line.

If the transmitter is left switched on, there will be a quasi-infinite series of forward and reflected waves, whose sums will converge to steady-state values. The source impedance and the line length will of course affect the relative amplitudes and phases of successive generations of forward waves. I believe the point you're missing is that source impedance and line length will *also* affect the relative amplitudes and phases of successive generations of reflected waves, in exactly the same way. Therefore the standing wave ratio - literally, the ratio of maximum to minimum voltages, caused by addition and subtraction of forward and reflected waves along the line - is *not* affected by the source impedance.

On the strength of recommendations here, I just ordered a copy of Chipman which is currently winging its way from New Zealand. But if you skip forward to "the detailed analysis of the resulting infinite series of multiple reflections... in Chapter 8", I do believe that is what you'll find.

Roy said something like this already, about a week ago; I've tried to say the same thing in a different way that might connect better with Chipman's explanation.

Of course you could arrive at the steady-state conditions much more easily by other methods. The infinite-series approach is an important check that the two approaches agree in the steady state, which of course they must.

Richard continues:
>The Challenge that I have offered more than several here embody such
>topics and evidence the exact relations portrayed by Chapman (and
>others already cited, and more not). The Challenge, of course, dashes
>many dearly held prejudices of the Transmitter "not" having a
>characteristic source Z of 50 Ohms.

No, it doesn't.

> Chapman also clearly reveals that this characteristic Z is of
>importance - only to those interested in accuracy.
>
No, I'm sure that what he really shows that source Z is of precisely *no* importance to SWR.

The source impedance *will* of course determine how much voltage, current and power the transmitter can deliver into a given impedance at its output terminals. That is obvious, but down the line it will affect the amplitudes of the standing-wave maxima and minima equally, so the SWR doesn't change.

>Those hopes having been dashed is much evidenced by the paucity of
>comment here; and displayed elsewhere where babble is most abundant in
>response to lesser dialog (for the sake of enlightening lurkers no
>less).

Please read that paragraph again, Richard... and you say *other* people
babble?

The reason no-one will take on your challenge is that it's an empty one:
the source impedance has no effect on the SWR, so there's nothing there
for us to prove.

> Clearly those correspondents hold to the adage to choose
>fights you can win. I would add so do I!

I'm not interested in "winning". All I'm interested in is getting the
facts right.

I guess I don't understand any of the above. Coherency just means the
signals are of the identical frequency. Coherency doesn't specify phase.
The phase of a reflected wave can be anything depending on feedline
length and load.

Well, Tom, as your education is "not worth mentioning", i don't
feel a need to impress or bore you with a lot of math. And a lot of
math is not needed in this case, although it would be interesting to
see the derivation of the conjugate equation.

Maybe you should play some more chess...

>
> Roy Lewallen, W7EL
[snip]

By semi-infinite I mean a line that starts at the generator and and extends out to infinity.
Clearly the driving point impedance of such a line is just equal to the surge impedance Zo.

But... if semi-infinite is unacceptable, why that's OK, just choose the length of Zo line you wish
and terminate it on the far end away from the generator with an impedance equal to Zo. This
finite line then has exactly the same driving point impedance as the semi-infinite line, namely Zo.

It doesn't really matter which line you choose to use, semi-infinite or finite length terminated in Zo.

The two lines are indistinguisable from each other at their driving points and along their lengths,
until of course you come the "end" of the terminated line. :-)

It doesn't matter if the lines are lossless, lossy, distortionless, or whatever. They just have
a perhaps complex surge impedance Zo(p) = sqrt[(R + pL)/(G + pC)] where R, L, C, and G
are the primary parameters of the line.

This line is driven by a Thevenin generator whose "internal" impedance is also equal to Zo.

That's all there is to it. Pretty simple stuff.

Now the generator's open circuit voltage is simply expressed as "2a" or just twice the
incident wave at the line's driving point.

i.e. if we use the symbol "a" to denote the incident wave at the driving point of the Zo line
[either the semi-infinite or finite terminated line is fine, the result is the same] this is just half
of the generator voltage.

There will be no reflected wave at the line's driving point, since there is an image match
[Zo-match] everywhere on the line including at the driving point. There is no reflection
at the driving point simply because the generator's source impedance is also Zo.

Now calculate the reflection coefficient at the driving point. You can calculate rho looking
in either direction, i.e. the so-called "front end", or "back end" reflection coefficient, it just
doesn't matter. Either take the Zo of the line as the load on the generator or take the Zo
of the generator as the load on the line, whatever...

In both cases the classical rho evaluates to:

rho = (Zl - Zo)/(Zl + Zo) or (Zo - Zl)/(Zo + Zl) it just doesn't matter, since the load
Zl is Zo anyway. Zl = Zo looking in either direction from the line's driving point and so...

rho is identically zero.

rho = (Zo - Zo)/(Zo + Zo) = 0

Zo is complex in general and rho must be computed either by an analog computer called
a "reflectometer" or by a human performing algebra, in either case the reference impedance
used to calculate rho is the complex Zo of the line.

The generator generates the incident voltage "a" by forcing the voltage "2a" across the
two impedances, i.e. the Zo of the generator and the Zo driving point impedance of
the line. The reflected voltage "b" across the line's driving point is identically zero
And... this is *NOT* a conjugate match, it is an image match. i.e. Zo staring at Zo
at the driving point, not Zp staring at conj(Zo).

If one then assumes that either the line, or the generator impedance, is replaced by a line
or generator impedance of characteristic equal to the conjugate of Zo then clearly in general
there will be a non-zero reflection coefficient and a non-zero reflected voltage.

This is a long winded explanation of a simple concept comprising a very simple circuit
containing an ideal generator, a complex impedance and a terminated line, along with
no more than a couple of equations that constitutes a clear and simple mathematical
and/or experimental "proof" that the reflected voltage is non-zero for a conjugate match
and is zero for an image match.

QED

Of course if one should choose a definition of the reflection coefficient different from the
classical one [Say like Slick's definition] and by inference a different definition of the reflected
voltage wave, then you can have b zero for a conjugate match. And it seems that some folks
like to go to hell that way.

I say anyone is entitled to go to hell their own way in making definitions but... they must
continue to be consistent with those definitions throughout if they want to calculate and/or
measure correct values.

Me? I like to use the classical defintion of rho and b, i.e. the ones that are null at an
image match point, where Zo is glaring at Zo, since that is what happens at every
infinitesimal length along Mother Natures' transmission lines. And she does not
allow reflections to occur where Zo meets Zo!

I believe that a definition system that defines there to be no reflections where Zo meets
conj(Zo) but reflections to occur where Zo meets Zo to be un-natural.

And I believe that you and I both agree.

[BTW... Aside: You do agree that one cannot tell the difference between a semi-infinite line
of surge impedance Zo and a finite line of surge impedance Zo terminated in Zo at it's finite
distant end by observations at the driving point, do you not?]

George, with all due respect, even if the SWR measurement was
done right at a short or open, the highest rho you could get would be
1.

If the power reflection coefficient is the square of the
MAGNITUDE of the voltage reflection coefficient, how can you have a
voltage RC greater than one without the power RC being also greater
than one??

> it... -10 points for the wrong method!
[snip]

Dave:

I disagree, I feel that for measurements and calculations involving the
impedance matching
dynamics at any reference plane in such systems the differences between
lumped and
distributed systems is trivial and unimportant.

The impedance matching dynamics at the reference plane/junction point are
the same for
distributed and lumped systems, they obey all the same equations, their
electrodyanamics
is the same, one simply cannot tell the difference at the driving point.

If you don't like lumped models, then make the internal resistance of the
Thevenin
generator out of a distributed line. It will work just the same way.

The disagreements that occur when there are discussions/arguments occur
because folks
often assume they are different situations, but they are not.

Every line has a driving point impedance of Zo and at that point the voltage
and current

are related by Ohms Law v = Zo*i just as for a lumped system of impedance Zo.
It simply doesn't matter if Zo is lumped or distributed when making observations at the
driving point. And this is what one is doing when making impedance matching calculations.

I agree that if you move off down the line in distance/space that you will find
differences, but you certainly can't observe them at the driving points.

A slotted line device for measuring VSWR is a physical example of a measurement
system that works on a distributed system that won't work for a lumped system.
However you can exactly correlate the measurements taken with the slotted line
to measurements taken at the driving point.

And so, although I agree with you that some can't seem to be able to see that these
situations are the same, I don't agree that makes them different. They are the same
at the driving point.

Verticals are low angle beasts and "look" low and "see" all the man made
wundernoise. Horinontals look up the sky, where not much man mades.
If you need to listen on low bands for DX, the best thing is to use Flag or
Pennat RX antennas, they give some directivity and discrimination against noise
sources around. But you should notice decent improvement on DX esp. on
transmit.
There is really no need to wait for grass to grow tall, just tie the wire down
and you can move the lawn short, they wiill eventually "sink" into grass and
ground.

In simulation programs, transmission lines are
solved for their two-port
parameters, and are then treated as lumped
circuits in the actual
simulation, just like any lumped-element circuit.
Which is a good way
to do it.

I notice that in the ARRL Antenna Book, 19th
edition , on page 24-7, it is stated with definite
finality that the reflection coefficient formula
uses the complex conjugate of Zo in the numerator.
I also understand that this has been established
by a "well-trusted authority".

I have used Mathcad to calculate rho and VSWR for
Reg's example, for many values of X0 (imaginary
part of Z0) from -0 to -250 ohms.

The data follows:

Note: |rho1*| is conjugated rho1, SWR1 is for
|rho1*|, |rho2| is not conjugated and SWR2 applies
to |rho2|

X0.......|rho1*|..SWR1.....|rho2|..SWR2
-250..... 0.935...30.0.....1.865...-3.30
-200..... 0.937...30.8.....1.705...-3.80
-150..... 0.942...33.3.....1.517...-4.87
-100..... 0.948...37.5.....1.320...-7.25
-050..... 0.955...43.3.....1.131...-16.3
-020..... 0.959...47.6.....1.030...-76.5

-015..... 0.960...48.4.....1.010...-204
-012..... 0.960...48.9.....0.997....+/- infinity
-010..... 0.960...49.2.....0.990....+305
-004..... 0.961...76.3.....0.974....+76.3
0000..... 0.961...50.9.....0.961....+50.9

The numbers for not-conjugate rho are all over the place and lead to ridiculous numbers for SWR. It is also obvious that for a low-loss line it doesn't matter much. But values of rho greater than 1.0, on a Smith chart correspond to negative values of resistance (see the data).

Something is wrong here that we are overlooking.

The use of conjugate rho is so much better behaved that I have some real doubts about some of our conclusions on this matter.

What about it folks? How can we get to the bottom of this?

[snip]

Nope, Hecht must be far too old and out of date.

These days there are instruments available that acutally observe and count photons one-at-a-time.

Perhaps these instruments did not exist in Hecht's day, but they do now!

[snip]

> "Evolution of the modern photon", Am. J. Phys. 57 (1), 27 (1989)."
[snip]

Yes it is! Most of the really good work occured in the 1990's.

Have a look at Am. J. Phys. and Physical Review, and Nature in the decade of the 90's.

Better yet, buy and read "Entanglement" it has the whole story and all of the references.

I still say...

[snip]
> > Deal with it!
[snip]

[snip]
> It just occurred to me that virtual photons might explain telepathy.
> What do you think?
> --
> 73, Cecil http://www.qsl.net/w5dxp
[snip]

You might just be right. Again read "Entanglement" and the case for "teleportation".

It has been "proven" in various labs throughout the world, i.e. MIT, CERN, U Maryland,
etc... etc... in many diverse duplications of the same experiments, all in the decade of
the nineties.

It 's not exactly the same teleportation as you might imagine since only quantum states
can be transferred over distance instantaneously, while conventional "information" is
limited by relativity to the speed of light.

The "strange world of quantum mechanics" has not been found to be wrong yet. So far
it has been able to predict any and all physical effects with no exceptions, while wave
dynamics cannot make such claims. Why waves can't even explain the old fashioned
hundred year old photoelectric effect! What's your point?

;-)

From your more recent posting, I misinterpreted what you mean by "driving point impedance". It's simply the impedance of the transmission line, not the impedance from the load looking back toward the source, nor the source impedance. Based on that interpretation, I'll try again.

Oops. No it's not. Consider circuit "A", a voltage source in series with a lumped impedance equal to r + jx. And circuit "B", a voltage source in series with a transmission line of length, say, one wavelength, with characteristic impedance Z0 = r + jx. The two are not at all equivalent. To show that they're not, connect a 50 ohm resistor to the output of each. The resistor current in circuit "A" is Vi/(50 + r + jx). The current in circuit "B" is Vi/50.

David Robbins recently made several postings explaining that these two circuits are not equivalent. Hopefully the above example illustrates that.

Can't you do your "proof" with, say, a one wavelength transmission line of characteristic impedance Z0?

The equation in the ARRL Antenna Book is identical
to the equation for rho that is in the Power Wave
literature (see Gonzalez and also see Kurokawa).
Also, numerous literature sources describe how an
open-circuit generator with internal impedance Z0,
connected directly to load ZL, is actually a power
wave setup that leads to a rho formula that is
identical to the formula in the ARRL Antenna Book.
When calculating rho, it is not necessary to fool
around with the wave equations, because frequency
is constant and everything is steady-state.

[snip]

Y'all are missing my point.

First off... you, and Dave have just changed situation I proposed. I did
not say
that there was an unterminated line of one wavelength! You and Dave said
that. Forget it. That has nothing to do with the discussion/proof!

Read my "typing"! I said you must have *either* a semi-infinite line, whose
driving point impedance is known by all to be exactly Zo, *or*, but it is
simply beside the point, if you must insist on using a finite length
line then that is OK as well as long as it is terminated at it's far end
in an impedance equal to Zo.

In either case of the semi-infinite Zo line or the finite line terminated in
Zo the
driving point impedance is identical, i.e. it is Zo and you can't tell the
difference
between the two at the driving point.

[snip]
> David Robbins recently made several postings explaining that these two
> circuits are not equivalent. Hopefully the above example illustrates that.
[snip]

I disagree with Dave. A semi-infinite Zo line and a finite Zo line
terminated
in Zo are indistinguisable at the driving point and at all points along
the lines, until you come to the end of the finite line, but even there the
voltage and current across then terminating Zo is identical to the voltage
and current at the same point on the semi-infinite line.

All of this discussion about there being a difference is moot. There is no
difference. That's exactly why I set it up that way, simply because there
is no difference. You guys are missing the point.

Check out any book on transmission lines...

When you look into the end of a transmission line of semi-infinite extent you
see a driving point impedance of Zo. That is the very definition of Zo!

If you cut the line off to a finite length and terminate it in it's characteristic
impedance Zo the driving point remains the same, i.e. Zo. That again is
part of the defining charateristic of characteristic or surge impedance!

Take a chunk of 50 Ohm lossless coax and terminate it in 50 Ohms. What's
the impedance you see looking into the end? 50 Ohms. Now change the length
to something else and again terminate it in 50 Ohms, what 's the impedance?
50 Ohms, it doesn't matter how long the line is if it is terminated in it's
characteristic impedance it's driving point impedance is Zo! End of story.

You simply can't tell the difference between a line terminated in it's characteristic
impedance and the characteristic impedance of an semi-infinite line as found by
observiations at the driving point, they are one and the same. Zo!

[snip]
> Can't you do your "proof" with, say, a one wavelength transmission line
> of characteristic impedance Z0?
>
> Roy Lewallen, W7EL
[snip]

Yep, sure can... sigh, why is this soooo hard.

Use a one wavelength line if you insist, but terminate it at the far end with an
impedance equal to Zo!,

The length of the line has nothing to do with the proof.

As a matter of fact that is one of the neat things about the so-called
"proof" I cooked up.

The "proof" is just about whether there are reflections at a conjugate
match or not.

The proof, mathematical or experimental, just proves that there are no
reflections [as defined
by the classical rho] when the generator sees it's image Zo, but there are
reflections when the
generator sees it's conjugate! And the same in the reverse direction. i.e.
there are no reflections
when the line sees it's image Zo but there are reflections when it sees it's
conjugate.

And if Zo is a real resistance say Zo = R, then both situations are
identical.

That's all, nothing complicated, simple straightforward stuff, when Zo is complex, there *will* always
be reflections at a conjugate match.

This means that when there is a conjugate match on a complex line a "classical" reflectometer
will not indiacate zero reflected voltage. And if the scale on the reflectometer is actually calibrated
in "Watts" even though it measures Volts, it will indicate the presence of [[a "false"] reflected power
at a conjugate match.

But then everybody already knew that!

QED!

Hi Cecil,

This shows the lack of your "optics." A laser which amplifies by
virtue of coherency, consists of a phase locked aggregation of what
would have been incoherent illuminations. It would be an LED
otherwise.

As I have said for quite a while now, it is a simple matter of
interference math. Such math shows everything of coherency or
differences. A coherent signal, is by definition of the same
frequency of another who matches that coherency.

To put it ironically, the challenge I offer is deliberately incoherent
to give that math a deliberate solution that is other than the result
of simple addition or subtraction.

Not QED at all. You claimed to have proved that maximum power is
delivered to a load when a transmission line is terminated such that the
reflected voltage on the line is zero. Here, you're agreeing that the
reflected voltage is zero when the line is terminated in its
characteristic impedance. So where's the proof that this condition leads
to maximum power to the load?

Hi Cecil,

I didn't forget that your source sees a non Zs load if it uses a low pass filter following its final that does not match it (very often the case and tolerated by the user unaware). If you are using a tuned final, fine, if not - heat. Matching problems don't stop at the only connector you have access to. If the designer of your rig did his job, matching is performed through the entire chain of amplification. At some point the heat of amplifying a mW to 10 mW is not terribly significant, but the mismatch can still present a mediocre signal compared to what you paid for, but someone else got.

In amplifiers (especially for AF), feedback deliberately discards gain to achieve a high degree of matching tolerance. Most Ham transmitters lack that kind of matching tolerance (there is no significant feedback for the purpose of maintaining gain stability, phase stability, lowered distortion, reduced noise,....).

All of this is something Dr. Slick aspires to, and yet he has not yet drawn together to present (or understand) coherently. Most can recognize these characteristics of feedback, but too many here simply bob heads without understanding how and to what extent it is accomplished. Inattention to interstage matching is simply sloppy, or employed with a cavalier attitude that you will be satisfied with "OK" rather than best.

>case) and a feedline inside the building hooked to another antenna.

In most cases you have to be quite close to the indoor antenna (within
a few meters), since the signal reradiated from the indoor antenna is
suffering an additional inverse square attenuation.

The worst situation for a passive repeater system is when the repeater
is in the mid path with the end stations A and B. The path losses
(expressed in decibels) from A to the repeater and from the repeater
to B are _added_. Compare this to the free space (line of sight
situation) in which the total path loss from A and B is only 6 dB more
than compared to the path loss for A to the mid point repeater
location.

In a passive repeater system, moving the repeater closer to the other
station, the sum of the path losses from A to the repeater and from
the repeater to B (expressed in decibels) will be smaller than with a
repeater in the mid path.

>I have not seen it but have heard that in long tunnels they have an outside
>antenna and an amplifier and some inside antennas for the FM radio stations.

Leaky coaxial lines are used as "antennas" in tunnels.

> same. They are not different as you suggest.
>
> Thoughts, comments?

yes, i still hold that they are different. they are from completely
different realms of electromagnetics. in the transmission line reflection
coefficient you are working with a distributed system that is modeled with
wave equations. there are delays, waves travel and reflections return after
a finite delay. in your example you have coerced the voltage and current
waves to be the same in the transmission line, but that is not the same as
modeling the line itself.

in the generator feeding a load you are looking at a lumped model. these
are normally not solved with wave equations, there are no delays or
reflections. the problem of calculating maximum power transfer from a
generator to a load of a given impedance is a simple problem solved with no
waves and only one pde used to find the max of the power to the load wrt the
generator impedance. it doesn't care what the load is, as long as it is a
linear time invariant impedance. now, you could create that impedance by
putting a load on the end of a transmission line and transforming it back
through the normal transmission line equations, but once you do that you
throw the line out and solve the simple equations in the lumped models.

these discussions always seem to end up in this same quagmire, one group
trying to solve everything with wave equations, sinusoidal steady states,
transmission line transformations, and the other holding on to the lumped
models and trying to make them fit the wrong problem domain. one thing i

did learn in ee classes was to use the right model for the job, choosing the wrong one will give you wrong answers most of the time.... the real problem is that sometimes you can get the right answer from the wrong model just because the numbers work out... and when you have to show your work you lose credit for using the wrong method but still getting the right numerical answer. that is what i see here, someone has started with a simplified case that just happens to work out to the same answer and has tried to generalize it... -10 points for the wrong method!

Hi Ian,

Are you the goat being used to clear land-mines? You should have awaited the arrival of that copy to arm your education before tentatively proceeding into no-man's-land. Sorry OM but this is my turf, and I was trained in the art. I don't need to trade on my credentials, because, as Chapman will reveal to you, it is not particularly remarkable until you reject the obvious and come up with indecipherable data. That data is found in the form of the solution to the challenge no one dare even test at the bench without the prospect of a glance over the shoulder as if it were an unnatural act revealing them in shame. How can you claim facts as a noble goal when you shy from calculation or testing? OK, you lack the calculation offered by Chapman, a significant chapter for you and others certainly; but is/are your bench(es) so poor as to restrict your experimentation? I am not persuaded by such poverty.

You also could have at least waited for George (who can observe both my argument and the text) to either blast me away, or confirm, so, in a sense, your progression is only of wounded ego as you really have added nothing to the discussion. (Your affirmations of my logic, even if unintended, are not informed enough.)

As for the other cowering giants, I still remain without an answer to my challenge such that even if everything I said were a pack of lies would still have a result. None even dare posit it is 3.27dB! What price courage? What inhibits any of those greats from supplying even a guess given that I bow to that attitude? One, it is incalculable in your philosophies; and Two, you lack the means to obtain two resistors and a hank of line. Either, for me, is the ultimate irony which steels my courage to withstand the petty repetition of "t'ain't so" offered in place of intellectual argument.

By the way, the source of the challenge is far more accessible and found in the libraries of many here. I withhold its citation to reduce the hazard of those books being tossed into the rhetorical bonfire of the vanities. Of course, this could lead to entire shelves being swept into the heap to avenge my discord. You appear to be in retrograde motion in that regard so you do have some redeeming features. Take care that your education doesn't lead you to the same pillar others would have me tied to. ;-)

Good luck Ian and

I've never had any luck using just one can. You could tie the string to a doorknob and use just one can - but what are you going to hear on it?

To make it work, have another can on the far end of the string, with someone speaking clearly into the can. Remember to keep the audio transmission line taut for best reception.

He squares it to get the magnitude of the vector. There is still a phase
angle
>
> How do you get more reflected power than incident power into a
> passive network, praytell??

You don't. at gamma =2.41, the phase angle is about 65 degrees, and the real
part of gamma =1.0

Now try this: using the conjugate formula, calculate gamma for the case
where the line is terminated in a short circuit, and tell us how that meets
the boundary condition.

==========
Dear Slick,

Not if the circular Smith Chart is extended outwards to a radius of 1 + Sqrt(2). Or more if you don't want to be restricted to transmission lines.

I have a vague recollection this has already been done by somebody who followed Smith for use with the higher values. I don't think Smith ever claimed any special properties for his chart. It was his employer, Bell System, who attached his name to it.

Smith produced his chart around 1939 to simplify line calculations at HF and above. His principal assumption/simplification was that only purely resistive values of line Zo were admissible. Also that lines were sensibly lossless. His starting point were charts (3-dimensional) which had been used as early as the 1890's to solve problems relating to design, installation and operation of power lines, telephone and telegraph lines. A Smith chart could be printed on a flat sheet of paper and at HF the small calculating errors were quite acceptable for engineering purposes. A valuable tool in those times.

The old original charts provided solutions to equations involving complex hyperbolic functions such as Sinh(A + jB) where A is line attenuation in nepers and B is phase shift in radians. For example, the input impedance of an open-circuited transmission line (or end-fed antenna wire) is (Ro + jXo)*Coth(A + jB) ohms which is a fearsome calculation by log tables or slide rule but much easier by chart. And can now be done in milli-seconds inside a simple computer program

Smith set Xo = 0 and A = 0 and be damned to the consequences - which you lot, floundering in the mire, valiantly attempting to get back to basics, are now suffering from.

Given a line's primary characteristics, R,L,C,G, length, or it's secondary characteristics Zo, dB, phase angle, plus the line's terminatiing impedance it is possible to calculate, by classical methods, all other quantities of engineering interest - WITHOUT ANY REFERENCE TO REFLECTION COEFFICIENT OR SWR which are mere man-made notions supposed to assist understanding of what goes on in the real world but, as exchanges on this newsgroup show, are just a pair of bloody useless nuisances.

Such is life. G4FGQ.

And if it is not an RF transmission line?
If it is a DC circuit? Say your phone line when on hook?
If it is a lamp cord?

Do we really need directional wattmeters to understand what is
happening?

Hi Cecil,

Two reflective interfaces with an aperiodic distance between.

The cable (or any transmission line) falls in between. So does most instrumentation to measure power. All fall prey to this indeterminacy (unless, of course, it is made determinant through the specification of distance, which it is for the challenge). As I offered, this challenge is not my own hodge-podge of boundary conditions, it was literally drawn from a standard text many here have - hence the quote marks that attend its publication by me. I am not surprised no one has caught on, I also pointed out this discussion is covered in the parts of Chapman that no one reads. Whatchagonnado?

The example of the challenge serves to illuminate (pun intended) the logical shortfall of those here who insist that a Transmitter exhibits no Z, or that it is unknowable (to them, in other words), or that it reflects all power that returns to it (to bolster their equally absurd notion that the Transmitter does not absorb that power). Chapman is quite clear to this last piece of fluff science - specifically and to the very wording. Engineers and scientists simply converse with the tacit agreement that the source matches the line when going into the discussion of SWR (and why Chapman plainly says this up front on the page quoted earlier). This is so commonplace that literalists who lack the background (and skim read) fall into a trap of asserting some pretty absurd things. It follows that for these same literalists, any evidence to the contrary is anathema, heresy, or insanity - people start wanting to "help" you :-P

Ian grasped at the straw that the discussion simply peters out by the steady state and wholly disregards the compelling evidence (and further elaboration of Chapman to this, but he lacks another voice, the same Chapman, to accept it) with a forced mismatch at both ends of the line. It is impossible to accurately describe the power delivered to the load without knowing all parameters, the most overlooked is

distances traversed by the power (total phase in the solution for interference). I put the challenge up to illustrate where the heat goes (the line); and it is well into the steady state, as I am sure no one could argue, but could easily gust
"t'ain't so!"
At least I saved them from the prospect of strangling on their own spit sputtering "shades of conjugation." [Another topic that barely goes a sentence without being corrupted with a Z-match characteristic.]

Using this example for the challenge forces out the canards that the source is adjusting to the load (in fact, the challenge presents no such change in the first place) and dB cares not a whit what power is applied unless we have suddenly entered a non-linear physics. None have gone that far as they have already fallen off the edge earlier.

Now, be advised that when I say "accurately" that this is of concern only to those who care for accuracy. Between mild mismatches the error is hardly catastrophic, and yet with the argument that the Transmitter is wholly reflective, it becomes catastrophic. The lack of catastrophe does not reject the math, it rejects the notion of the Transmitter being wholly reflective. This discussion in their terms merely drives a stake through their zombie theories.

I would add there has been another voice to hear in this matter. The same literalist skim readers suffer the same shortfall of perception. We both enjoy the zen-cartwheels so excellently exhibited by the drill team of naysayers. ;-)

Hi Cecil,

You have expended far more time climbing Everest in search of the
guru, than simply doing the challenge at the bench.

Do you trust your own work? If not, how many Everests would you climb
before you accepted their word? Best 3 out of 5? 5 of 7? ....?

Any negative evidence would put the kibosh on this challenge, I would
think. Then we could all write the editors of that reference and ask
them why they included such trash.

What?

Think of the savings in fewer knees to patch and scuffed boots. ;-)

Hi...I've been looking around for one of the older Swan Transcevers...It is The Model 250C
6 Meter Unit, with if possible the Matching AC Supply...I'm not looking for a basket case, however. the radio does not have to be Mint either ! Also the price has to be reasonable...or else I might as well go out and but one of these new Icom mobile radios with multi-mode VHF-UHF-6 meters-and HF to boot !!...for some $ 725.00
Anyway if someone out there has one of these radios ...please drop me a line and we can go from there...OK

Thanks a Lot

4467. Calculus not needed (was: Reflection Coefficient Smoke Clears a Bit)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-29 05:31:02 UTC
From: ryeburn@sfu.caz
Message-ID: <ryeburn-2808032231020001@bni030qny8kc.bc.hsia.telus.net>
Source record: 109413

I've enjoyed reading this and related threads. Some comments have been made about using calculus. Though I spent a significant portion of my pre-retirement life attempting to teach that subject to undergraduates, I don't believe in using calculus whenever simple geometry and/or algebra makes it unnecessary. A proof that avoids calculus can be meaningful for those who don't know calculus, or who haven't used it for a while.

With that said, I have a few comments to make about some of the assertions I have read here recently, some of which have appeared without explicit proof.

(1) The surge impedance of a (lossy) transmission line cannot have an angle more than 45 degrees away from the real axis.

This is true. Z_0 = sqrt((R + jwL)/(G + jwC)) (here I am using "w" instead of omega). Both the numerator and denominator lie in the first quadrant, so their quotient lies in the right half plane (angles subtract when one divides), and the square root of that has an angle lying between - 45 degrees and + 45 degrees. (The branch of the square root with positive real part has to be taken; if you can find coax whose surge impedance has a negative real component, I'll pay you good money for it.)

[Since this angle lies between - 45 degrees and + 45 degrees, peculiar consequences deduced from calculations involving surge impedances such as 50 - j200 can be ignored.]

(2) There is a nice geometrical interpretation for the reflection coefficient, or rather for its magnitude. Since the coefficient is (Z_L - Z_0)/(Z_L + Z_0), its magnitude expresses how much further Z_L is from the surge impedance Z_0 than it is from the negative, - Z_0, of the surge impedance. If Z_L is equidistant from Z_0 and - Z_0, then the magnitude of the reflection coefficient is 1. If Z_L is closer in the complex plane to Z_0 than it is to - Z_0, then the magnitude of the reflection coefficient is less than 1. If Z_L is closer to - Z_0 than to Z_0, then the reflection coefficient's magnitude exceeds 1. Now plot the points Z_0 and - Z_0 and draw the perpendicular bisector of the segment joining them. If Z_L is on that perpendicular bisector, the magnitude of the reflection coefficient is 1; if it is on Z_0's side of the bisector, the magnitude is less than 1; if it is on - Z_0's side, the magnitude exceeds 1. Of course Z_L has to stay in the right half plane; if it didn't have to do this, you could take Z_L very close to - Z_0 and get enormous reflection coefficient magnitudes.

(3) Consider an ellipse having Z_0 and - Z_0 as its foci. There are infinitely many such ellipses, including a degenerate one (just the segment between the "foci"). All these different ellipses fill up the

complex plane, and no point in the plane is on more than one of them. On any one such ellipse, the sum of the distances from a point on the ellipse to the two foci Z_0 and - Z_0 is constant (definition of an ellipse), the value of that constant depending upon which ellipse it is but the constant has to be at least as large as the interfocal distance. We should ignore points on the ellipse that are in the left half plane. A portion of the ellipse will be in the same quadrant as Z_0, and a portion will be in the quadrant that contains the conjugate of Z_0. (Remember we are ignoring the points in the left half plane.) All of the points on the ellipse that are in Z_0's quadrant are closer to Z_0 than to - Z_0, so they'll give reflection coefficients with magnitude less than 1. So will those of the points on the ellipse in the other quadrant under consideration that are between the real axis and the perpendicular bisector. But those that are between the perpendicular bisector and the imaginary axis will be closer to - Z_0 than to Z_0 and thus will yield reflection coefficients with magnitudes greater than 1. It should be obvious that, along any given ellipse, the one for which the magnitude of the reflection coefficient is greatest is the one on the imaginary axis, since as we move along the ellipse towards that point, the distance to - Z_0 decreases and the distance from Z_0 increases (remember, their sum is constant along the ellipse). So on any *one* ellipse, the largest reflection coefficient magnitude occurs where the ellipse meets the imaginary axis, and thus Z_L has real part 0 and imaginary part of opposite sign to that of Z_0.

(4) Start with Z_0 real, and slowly rotate Z_0 into either the first or fourth quadrant, but not more than 45 degrees in either direction, keeping the same magnitude while you rotate. The segments joining Z_0 and - Z_0, their perpendicular bisectors, and the various ellipses will all simultaneously rotate. It's now obvious that for ellipses of any fixed size, the one producing the largest magnitude for the reflection coefficient will occur when Z_0 is at + 45 degrees or - 45 degrees. So if we want to maximize the reflection coefficient magnitude, we can restrict attention to those two cases. The - 45 degree case (capacitive surge impedance) is the more familiar one, but the math is the same either way. The only question is, which one of the ellipses should we use, if we wish to maximize the magnitude of the reflection coefficient?

(5) So now we're going to assume Z_0 = k(1 - j), and thus - Z_0 = k(-1 + j), while Z_L = ktj. It's clear that the factor k is going to cancel out when calculating the reflection coefficient, so I will henceforth ignore it (i.e., normalize it to k = 1 by appropriate choice of units). If you are of a geometrical turn of mind, you can produce a geometrical argument showing that the best one can do is to make sure the ellipse meets the imaginary axis at the same distance from the origin as the two foci, i.e. at j*sqrt(2). If you are of an algebraic turn of mind, you can make an algebraic argument involving completing the square to demonstrate the same thing. If you insist on using calculus, it's now just one variable calculus, not multivariable calculus, since the only independent variable is t, which will turn out to be sqrt(2) at the maximum. (Hint: don't look at the ratio of distances; look at the square of that ratio, so as to get rid of all those square roots.)

(6) Once all that is done, it's just a bit of algebra to show that when t = sqrt(2) then the magnitude of the reflection coefficient is 1 + sqrt(2). That's the best (worst?) you can do. And if you can find some coax whose surge impedance angle is - 45 degrees, you can indeed do it.

All the above was done from first principles. I am not fortunate enough to own a copy of Chipman, though I wish I were, but if this is what he says, then I am in full agreement with him.

David, ex-W8EZE, willing to part with some of my pension money for a copy of Chipman if you know where one can be found (Powell's doesn't have any copies)

Well, I really was hoping I'd shame someone (especially Garvin) into
actually going through the math exercise. It's not all that
difficult, and as you've said before, and as I agree, they'd benefit
from actually doing it, and also from thinking about what's going on.
Some of the more subtle physics (such as phase shifts associated with
skin effect) isn't so easily accessible, but surely these things are
to those who are willing. It seems like everyone agrees fairly
readily that Zo=Vf/If=-Vr/Ir (to a good approximation, anyway), and
also to the couple other things you need to let you find Vr/Vf, but
things rather rapidly seem to fall apart along the way to Vr/Vf. I've
given up trying to understand why, Reg, so I might as well get a bit
of dry humor out of it all.

Actually, I think you _did_ state the value once or twice recently in
these annals.

Cheers,
Tom

Still playing with this antenna to get things sorted out, but I'm
using a 44-ft. dipole with 42-ft. of twinlead. 10m is tuning at 000 on
the inductor; 12m, 15m, 20m are at 003; 30m is at 013. Looks like,
then, 000 is minimum inductance.

Thanks to all...

When looking for a copy yesterday, it seemed incredible that none of the major US dealers had even one for sale.

However, copies might also have been catalogued under "Schaum" as the author, the book being one of the Schaum's Outline series.

I only discovered this possibility when it was too late to do anything about it, so it may be worth a second look at the US dealers.

Do I have this right?

Dr Slick examined the generally accepted formula for rho
and learned that its magnitude can be greater than one.

This appears to imply that reflected power is greater
than incident; something that would violate various
conservation of energy laws.

Dr Slick has therefore rejected the generally accepted
formula and produced one which does not result in
more power being reflected than is incident, thus
satisfying various conservation of energy laws.

Many people took issue with this redefinition of rho
and attempted to show why the generally accepted formula
is correct.

But that does not address the issue with the generally
accepted formula; how can reflected power be greater
than incident?

A clear explanation of why rho greater than one
does not violate conservation of energy would seem
to remove Dr Slick's objection to the generally
accepted formula and then everyone could agree
on the formula.

I doubt that any proof of the correctness of the generally
accepted formula will convince Dr Slick until it is
shown why it does not violate conservation of energy.

Your tin can will work much better if you add a piece of tissue a coil of wire and a magnet. I don't know why no one ever mentions that when talking about the finer points of tin can technology.

Well I guess a passive repeater was exactly what I was thinking of and it sounds like it works about as well as one would expect. Is there such a thing as an active repeater? Is there some way that I can amplify all of those signals. Can I broadcast all frequencies all the time?

Also, I'm still interested in grounding. I've been noticing the effects of grounding more and more lately. I just realized that my house isn't really grounded (as far as I can tell anyway). I've got PVC plumbing and the electric box is just wired neutral to common. Ever since I put a ball on my truck and wired up the trailer light connecter I've gone from great reception on the radio to average or poor. I think the trailer ground wire is acting like a maverick antenna. We got a new forklift that has a fiber strap that drags along the floor. I think the wheels are polyethelene or polypropoline or something and without the strap the forklift can generate enough static electricity to knock you on your ass. I lived in Okinawa when I was a kid and a lot of the cars there had a rubber strap with a little reflector that drug along the ground. The explanation at the time was that the Japanese liked lights. I never did understand but could it be to ground the vehicle and get better radio reception? Should I drag a chain behind my truck for better reception? Also, the radio at work; how should I set the antenna up. It's just two pieces of wire tucked up into the ceiling tile. There is a copper compressed air line running nearby that is not grounded directly (It is hung from the structual steel but there is no direct copper to ground). I've noticed that sometimes reception is a lot better if one or both ends of the wire are touching this copper line. Is the antenna being grounded or is it acquiring capacitance? WHat is the proper way to ground it. Do you ever ground an antenna or do you just ground the receiver?

Well that's probably too many questions already. I'm posting via google so i have to wait 3 to 6 hours to see it.

Thanks,
El Malo

and not that anyone is going to tell me but what is 73?

Nevertheless, the outer circle of the Smith chart
is *always*
the locus of zero positive resistance and infinite
SWR, and a rho vector cannot terminate on, or
cross over, this circle when a load R>0 is
present, regardless of the rest of the circuit,
including any possible combination of resistances
and reactances and complex Z0.

One can argue "ignore rho=1 and just jump over
it". This cannot be done in good mathematics.

Dismissing rho and SWR as "contrived nuisances" is
a convenient way to get rid of this problem, but
it does not "wash". Rho and SWR are fundamental
properties of transmission lines that do not go
away, and a non-zero R precludes rho=1.0.

Any attempt to circumvent (bypass) these small
inconveniences is doomed to failure, regardless of
the analytic geometry considerations.

There is no NET power at the zero crossings. There exists
equal amounts of power flowing in opposite directions as
represented by the forward Poynting vector and the reflected
Poynting vector. Those two power flow vectors simply cancel
at the NET power equal zero point.

Hi, Yuri:
Forgot to say that the soil surface is uneven enough that even hairpinning the radials down wasn't as good as waiting until they were sufficiently buried by grass cuttings so as not to be snagged by blades.

On the flags and pennants, I've read the stuff on various websites. The stumbling-block for me is that nobody around here (Cincinnati) has any experience, good or bad, or they ain't talkin', and I gather that these devices are really site-sensitive wrt soil conductivity.

Any insights?

TIA & kind regards,
Dave, N3HE

Power wave theory avoids the Smith chart, since
there are no transmission lines. Scattering
matrices are used instead. Nevertheless, rho is
still an important parameter, but it does not
involve distance separation between generator and
load as a parameter.

Why didn't you do the gamma for a shorted line using your formula? I think you settled on (Zl - Z0*)/(Zl + Zo). For Zl = 0 this comes to -Z0*/Z0, which, for Zo having phase angle b equates to -1 at angle(-2b).

This is in more detail of what ACF do:

1. Normalize the RC to (Zn -1)/(Zn +1)
2. Let's say we agree that for biggest magnitude, this has to be in the left hand plane.
3. Draw a vector for Zn = a at -135 deg
4. Draw vectors for Zn - 1 and Zn +1. Note that these 3 vectors have the same y coordinate.
5. You now can draw two triangles with the corners at 0, Zn, and Zn -1 for one, and 0, Zn, and Zn+1 for the other.
6. Solve for Zn+/-1 in terms of "a"
7. By plane geometry the magnitude of, of Zn -1=
SQRT(1 + a^2 + aSQRT(2))
8. The magnitude of Zn +1 is
SQRT(1 + a^2 - aSQRT(2))
9. Square both sides of the equation, and gamma^2=
(1 + a^2 + aSQRT(2))/(1 + a^2 - aSQRT(2))
10 This equates to 1 + (2SQRT(2))/((a + 1/a) - SQRT(2))
11 |Gamma| max occurs when (a + 1/a) is a minimum, which is 2 at a=1.
12|Gamma| max is 1 + SQRT(2)

They anticipate people being concerned about |Gamma| > 1 and later come up with a formula for time average power. I don't know that looking at it is going to give anybody any insight, but for this is what they end up with (I am typing CM for Gamma):

= (1/2)Go|V+|^2e**(-2az)[1 - |CM|^2 +2(Bo/Go)Im(CM)]

Remember, z is distance from the load.

> (or, if you prefer, NET voltage and current).

That's true for two batteries. That's not true for transmission lines where Z0 forces the ratio of the traveling waves to be V/I=Z0. If you could use circuit math on transmission lines, there would be no need for transmission line math, Smith Charts, etc. You are allowing your shortcut to try to dictate reality. That won't work. Assume a constant V/I ratio is forced on each battery in your circuit and see what you get.

> Let me make it simpler then: the lamp cord from the wall to the table
> lamp; lamp off and lamp on. Most lamp cord looks like twin-lead; some
> have said it is approximately 100 Ohms but for the purposes of
> discussion feel free to assume any convenient Z0 for the cord.

I don't think you understand the problem. That lamp cord is about 0.0000005 wavelength at 60 Hz. Any reflected wave effects are completely negligible. It's like expecting reflections due to resistor leads at HF RF. They are theoretically there but usually too small to measure.

> And if it is not an RF transmission line?
> If it is a DC circuit? Say your phone line when on hook?
> If it is a lamp cord?

The transmission line has to be a non-negligible percentage of a wavelength for one to have to switch from circuit math to transmission line math. What's the wavelength of DC? What's the wavelength of voice audio? What is the wavelength of 60 Hz?

If the phone line is an appreciable percentage of a wavelength, there will be reflections (echoes) as anyone doing a transcontinental phone call can attest. Echo cancellation is big business with the telephone companies. Your theory would make telephone line echoes impossible for long unterminated lines. It is known that unterminated telephone lines result in the largest magnitude of echoes.

It just occurred to me that you can revolutionize the telephone industry if you are right. You could patent your idea of no reflected energy on a long unterminated telephone line and sell it to the telephone companies for millions of dollars. Just have every intercontinental telephone line unterminated by using high impedance receivers on each end. Since no reflected energy could cross the voltage minimum point, echoes would be eliminated without the expensive echo cancellation equipment.

> Do we really need directional wattmeters to understand what is
> happening?

No, one can learn the principles of EM waves and transmission lines
and alleviate one's ignorance. I am capable of estimating the
forward power, reflected power, and SWR on my 450 ohm window line
without actually measuring it.

> Please, replace wall outlet with lamp cord to table lamp.

Are you capable of measuring the 0.0001 degrees of phase shift
between the forward wave and reflected wave? Your measuring
instrument needs to be about plus or minus 0.0000001 degrees
to get an accurate measurement.

That won't do it unless the distance between them is somehow
dynamically changing. For fixed distances, steady-state signals
will be coherent.

This is a convenient rule-of-thumb, nothing more. It solves the
problem of something being unknowable. A source obeys the rules
of the wave reflection model. Unfortunately, we don't usually
know the exact value of source impedance seen by the reflected
waves. Thus, the rule-of-thumb.

I agree with Chipman on that.

> Now, be advised that when I say "accurately" that this is of concern
> only to those who care for accuracy.

That's the part I don't understand. You can assume a whole range of
impedances for the source while the forward power and reflected power
remain the same. Is "accuracy" somehow involved with efficiency?

>
> They changed the course just from one email from YOU? LOL!

Ah, Garvin, thank you for confirming once again that you don't
actually read what others post, even though you do respond abrasively,
childishly. Rex is their Engineering Director. He didn't say they
changed the course because of me, he said he couldn't find the formula
with conjugate in it in their "more popular course which covers linear
RF circuits," and they are now (and have for some time been) teaching
it with the unconjugated formula. He also said their course is based
on Gonzalez (see 1 below), a book that's been recommended to you by
some other posters. That was all in my posting of his reply to my
query, to which you responded, so presumably you actually read it.

I suppose in your mental state you believe that anyone who doesn't
agree with you is a nobody. Has that reduced you to posting
misrepresentations of what others have said, as you have here? Has
that reduced you to calling honest people liars? I have a good friend
who is schizophrenic, and he is rather that way. He lives in a
fantasy world which his mind has created for him, and to him it's
reality. It has taken quite a toll on him in other ways. It's very
sad to see. It's a disease I wouldn't wish on anybody. I hope you
are not suffering from the same disease, though I honestly do see
strong similarities in the way you respond to people.

The lone argument you have given (for a |Vr/Vf| not greater than
unity) is based only on your intuition, and just as intuition fails us
for some other physical phenomena, it does in this case. Those who
have gone through a careful development of the model we use understand
all this. Why are you even worried about it? It's pretty clear to me
you have no real interest in using or understanding it.

Cheers,
Tom

(1) From Rex's email: "This is in agreement with Guillermo
Gonzalez's text, "Microwave Transistor Amplifiers," which is one of
the references used in writing
the course."

El Malo,
The 'static' strap draggin on the ground is a terrible
idea. In most cases, it generates more static than it will
ever 'cure'. It's also dangerous, just like the fork lift.
The DOT prohibits static straps on commercial vehicles that
carry flamable/explosive materials (fuel trucks) because they
act as part of a "VanDegraff"(sp) generator. I'm sure a nice
fat spark is exactly what you want to see when connecting a
fuel line to a tank. (Also why fuel hoses at gas pumps are
grounded through the nozzle. And why fuel trucks at an air-
port always connect a ground line to the plane before fueling.)

>
> So are you saying that like charge does not repel?

No, I'm not saying that at all. In fact, there may not be any charges crossing the NET voltage = zero point and there doesn't have to be for energy to be flowing in both directions. Two waves flowing in opposite directions in a constant Z0 environment superpose but have no effect on each other. You are continuing to be confused by the NET values. Did you take a look at that Java-driven web page that I posted a couple of days ago. If so, I don't see how you could still be confused.

As an analogy, consider two equal magnitude Tsunami waves flowing in opposite directions in the ocean. According to you, these waves will reflect off of each other. But it is known that those two waves will simply flow through each other and continue their original paths unabated. A single carrier water molecule may only move vertically and not horizontally at all during this process.

You continue to confuse NET charge carriers with component energy.

4493. Off Center Fed Dipole: Windom HSQ

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-29 16:17:10 UTC
From: Charles Wittnam <wittnam@bresnan.net>
Message-ID: <a0L3b.296397$Ho3.42093@sccrnsc03>
Source record: 109337

I have an off center fed dipole that was made by Antennas and More. I am very aware of the hype surrounding the overblown claims for such antennas and their inherent problems. (radiating feed lines, etc.) What I was not ware of is the problems with getting basic information about the antenna from the "manufacturer." What I have is a 132 foot off center fed dipole they refer to as the Windom HSQ. What I am trying to decipher is what type of balun they are using. In their literature they refer to a 1 to 1. This can not be. From the location of their balun which is about 48 feet from one end, I am guessing that they are trying for the illusive 200 ohm impedance point for 80 meters and that the balun may be a 2:1. This company does NOT return any calls. I was trying to figure if I could cut this antenna down to a 40 meter version, which might be possible with a 2:1 balun, but not a 4:1. Anyone have any experience with this type of antenna?
Thanks.

I was wondering if passing a coaxial cable used for antenna very close to electronics like TV, stereo, etc. will cause some intereferance that could penetrate inside? I need to run the cable to balcony for my antenna and electronics are in my way.

The balun is probably a 4:1 and the antenna should work pretty well on
40m with an antenna tuner without any cutting. Borrow an MFJ-259B and
see where it is resonant.

>--

Hi Cecil,

This is a real (the example of the challenge) issue of the Mismatch
Uncertainty. It is only uncertain insofar as most folks are unaware
of the contribution of error the source presents, and doubly unaware
of the phase distances between the interfaces.

Accuracy is unrelated to efficiency, both valuations exist distinct
from the other. You can be efficient but express it with poor
accuracy or good accuracy, efficiency cares not a whit about your poor
situation to resolve it. You can also be pristine accurate and
horribly inefficient, here again, accuracy is not a function of
efficiency, accuracy cares not a whit about your waste.

As for your conjecture
>You can assume a whole range of
>impedances for the source while the forward power and reflected power
>remain the same.
I assume nothing, but I can portray the range through the same
challenge's example. It merely involves moving the SWR measurement.
I have already demonstrated that.

David:

[snip]
> sorry, not always... another clear generalization from oversimplifying and
> applying the wrong model. there are cases where there is zero reflected
> voltage for a conjugate match.
[snip]

David, my friend as I stated several times, there is only one such case NOT
"cases"
and occurs only when Zo is purely resistive.

In that case the conjugate is non-existent! What's your point?

Wanna proof:

The reflection coefficient is identically zero,

rho = (Z - Zo)/(Z + Zo) = 0

If and only if the numerator of rho is identically zero.

(Z - Zo) = 0

Solving for the unknown Z, this occurs whenever.

Z = Zo

For complex Zo = ro + jxo, conjugate match occurs whenever
Z = ro - jxo and so rho can only be zero when:

ro - jxo = ro + jxo

which only occurs when

-xo = xo

This can only happen if xo = 0, i.e. the reactive part of both Z and Zo
are identically zero.

i.e. -xo = xo if and only if xo = 0

And this only occurs when Zo is real, not when it is complex!

What exactly is your point?

Hi Jim,

I take it you don't know what heat loss the cable sustains. This has stumped everyone so far. They don't even grasp the straw of the first solution for a matched source. I imagine that their astrologers have advised them to not guess. (Why? Because a mismatched source might cool the line? ;-)

Would you care to try the challenge as a lesser goal instead of searching for the meaning of life?

You'll only have a problem if you're running a lot of power and the shielding is poor quality, or if there's current on the outside of the coax. Current on the outside can be reduced with a "current" or "choke" balun.

Hi Cecil,

Yes, it is terribly cryptic: how much heat is lost in the line?

It requires advanced techniques in measuring power lost over a known stretch of transmission line. This is an art unknown to many here and baffles them in how to proceed when written directions are provided.

Even if they reject those methods and directions, they struggle through massive tomes to come to no conclusion. What's more, the example resides in one of their cherished scriptures that many would swear by and would scream outrage at the suggestion that they might read it.

The irony is delicious.

[snip]

No I did not! Never said that, never have. Where did you get that idea?

I said that for a general complex Zo the reflected voltage is generally
NOT zero at maximum power transfer.

To make myself perfectly clear, let me repeat that...

I said that for a general complex Zo the reflected voltage is generally
NOT zero at maximum power transfer.

I said that for a general complex Zo the reflected voltage is generally
NOT zero at maximum power transfer.

I said that for a general complex Zo the reflected voltage is generally
NOT zero at maximum power transfer.

[snip]
> Here, you're agreeing that the
> reflected voltage is zero when the line is terminated in its
> characteristic impedance. So where's the proof that this condition leads
> to maximum power to the load?
>
> Roy Lewallen, W7EL
[snip]

What I was trying to prove was that the reflected voltage is NOT zero
at conjugate match for the case of complex Zo!

I proved that by setting up a transmission line with perfect image [not
conjugate]
matching on both ends [Zo is seen looking in both directions from any point
in
the system] and driven by a generator set up to create the incident wave.

That system has no impedance discontinuities anywhere. The impedance
is Zo all along the line and into the generator looking in either direction.
No impedance discontinuities no reflections, period!

I then calculated the classical reflection coefficient and showed it to be
zero
confirming that rho = 0 when there are no impedance discontinuities and the
classical formula for rho is used, rho = (Z - Zo)/(Z + Zo).

As the last step I changed the termination from Z0 to conj(Zo) i.e. a
conjugate
match, NOT an image match and showed that rho is NOT zero in this case.

QED!

Summarizing...

Image Match: A line of surge impedance Zo terminated in Zo has no impedance
discontinuities and no reflections.

Conjugate Match: A line of surge impedance terminated in conj(Zo) has an
impedance
discontinuity and hence has reflections. [Unless in the one unique case
that Zo is purely real]

BTW...

Aside: From the postings of Dave and yourself along this thread, I get the
impression that
ya'll beleive that lumped systems obey different laws and should should be
modeled
differently than distributed systems. I am surprised by that claim. Surely
you don't mean that!

Surely all electrical systems, lumped or distributed, must obey the laws of
electrodynamics as set
out by Maxwell-Heaviside. Do you know of any cases where they don't?

Regards,

Well, since the NET voltage is always zero at a voltage node when
the forward power and reflected power are equal, the instantaneous
voltage is always zero, i.e. the steady-state voltage is always
zero. If we have equal power flow vectors in opposite directions,
the NET power is zero at all points up and down the line.

[snip]

A 1volt step voltage in series with a zero length transmission line terminated in a 1 Ohm resistor!

Dave, all electrical systems, lumped and distributed alike, obey the Maxwell-Heaviside equations. They are all the same, not different as you claim!

Prior to Maxwell [mid 1800's] folks believed that lumped and distributed systems might obey different laws, but ever since Maxwell wrote down his celebrated 22 equations, using quaternions, and Oliver Heaviside reduced them to 4 neat little vector differential equations back in the mid 1800's, most everyone, with the apparent exception of yourself, has accepted that lumped and distributed systems obey the same laws!

What exactly is your point?

Do you believe that lumped systems are described by different laws than distributed systems? Are you trying to convince me of that 150 year old discredited idea?

All macro - electrical systems confirm to the same laws of electrodynamics, namely the Maxwell-Heaviside equations.

The only systems where Maxwell-Heaviside fails to predict physical reality is when dealing with the "very" small, i.e. quantum mechanics when one has to do Engineering and make predictions and design one-photon-at-time. In this case you have to use quantum electrodynamics or QED but still all systems, lumped or distributed must obey QED and Maxwell-Heaviside is just a special case or approximation to QED laws in the aggregate when there are lots of photons.

Dave you will have a lot of arguing to do to convince modern electro-technologists that lumped systems obey different laws from distributed systems. Or that the equations of lumped impedance matching are any different from transmission line impedance matching. They are the same! The models

are the same, the mathematics are the same, the experiments
confirm that they are the same.

Exactly what is your point?

> challenge's example. It merely involves moving the SWR measurement.
> I have already demonstrated that.

But: "Every time you make a measurement, you make an error." So said
my EE prof almost half a century ago. I assume it's still true. :-)

My goal is to be error-free on paper before I start the experiment.
Consider the following two examples:

1. The source is generating 100 watts and 20 watts of the 50 watts of
incident reflected power is being re-reflected in phase from the source.
The forward power meter reads 120 watts. The reflected power meter reads
50 watts.

The conventional rule-of-thumb has the source generating (100-30)=
70 watts since it is dissipating 30 watts of reflected power.

2. The source is generating 110 watts and 10 watts of the 50 watts of
incident reflected power is being re-reflected in phase from the source.
The forward power meter reads 120 watts. The reflected power meter reads
50 watts.

The conventional rule-of-thumb has the source generating (110-40)=
70 watts since it is dissipating 40 watts of reflected power.

How can you possibly distinguish between the above two identical conditions
caused by different source impedances?

Rho and SWR are usually not (bloody) useless nuisances. In the realm of ordinary applications of low-loss cable, they give very useful information. Under these conditions the Smith chart is a marvelous tool. Also, solutions of the exact complex hyperbolic equations, using the computer and complex Z0, can give information of several kinds that the Smith chart does not do very well.

For a moderately complex Z0 (moderately lossy cable), the conventional formula for rho can have magnitude values a little greater than 1.0. The boundary of the Smith chart represents rho=1.0, but a complex Z0 can push rho a little beyond the circumference. Because SWR is extremely high at the outer circle of the Smith chart, we should avoid that region in our work with the Smith chart.

Within these mild constraints, using the complex value for Z0, the conventional formula for rho is quite satisfactory. Ordinary coax with a matched loss of, say 2 dB (a guesstimate)or less per 100 feet, can use that formula, with very little (or acceptable) error. At the outer circle, where SWR becomes very large, the concept of SWR becomes rather useless anyway. I suggest use SWR on a Smith chart up to about 7.

It is enough to be aware of the problems associated with complex Z0, and to use the

approximate complex Z0 in the formula for rho.
Also, recognize that small errors in electronic measuring instruments become, at some point, important factors in the calculations.

In the case of rather lossy cable, it is best to abandon rho and SWR before they become "bloody useless nuisances", and use the computer for everything.

This is from your posting of August 25:

Roy:

[snip]

>> No one from "Camp B" has given any justification for the assumption that
>> the condition for minimum reflection is the condition for maximum power
>> transfer. We're lacking either a proof, a derivation from known
>> principles, or even a numerical example. I maintain that this assumption
>> is false.

[snip]

I did just that in a separate posting on this thread a couple of days ago.

Then on August 26, I posted:

> . . .

I'll restate something I mentioned before (first incorrectly, then
corrected). Connecting a load to a transmission line which is the
complex conjugate of the transmission line Z0 does *not* guarantee
maximum power delivery from the source, or to the load. The load
impedance which provides maximum load power is the complex conjugate of
the impedance looking back from the load toward the source. That
impedance is the source impedance transformed through the transmission

line between source and load, and it's not generally the same as the line's Z0, or its complex conjugate. When this condition of maximum load power is met, there will almost certainly be voltage and current wave reflections on the line -- there would be none only if the optimum load impedance coincidentally happened to be equal to the line Z0. So the argument that there can be no reflection of the voltage wave under the condition of maximum power transfer is wrong.

You didn't show differently in your analysis, and no one has stepped forward with a contrary proof, derivation from known principles, or numerical example that shows otherwise.

To which you replied, also on August 26:

Yes I did. I guess that you missed that post.

I haven't been able to find this proof in your postings.

>
> I said that for a general complex Zo the reflected voltage is generally
> NOT zero at maximum power transfer.

Well, shoot, I agree with that, as I always have.

> you don't mean that!

I believe you can build a bad or inappropriate model with lumped or distributed components, and draw invalid conclusions from them. Perhaps you missed my posting a day or two ago where I pointed out that your model using lumped components was clearly not the same as one using a transmission line, by means of the very simple test of observing the current in a load resistor.

And yes, lumped systems should generally be modeled differently than distributed ones.

>
> Surely all electrical systems, lumped or distributed, must obey the laws of
> electrodynamics as set
> out by Maxwell-Heaviside. Do you know of any cases where they don't?

This argument of "you don't agree with my view of how things work, or my inappropriate models, therefore you don't believe in the Laws of Physics" is as tiresome as it is pompous.

4517. Antenna computor modeling analysis

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-29 20:10:55 UTC
From: aunwin@insightbb.com
Message-ID: <85ed38d.0308291210.5fdcc622@posting.google.com>
Source record: 109361

When modeling a particular antenna and reviewing the
current flow on a particular radiator that was
interupted by a gap (small capacitor) it was noticed
that the current values showed a flutter or cyclical
current curves (positive values with cyclical deviation)
before the smoothed out to a normal current curve,starting
at the capacitor gap
Anybody have any idea what this represents as opposed
to an assumption that it was all misprogrammed?
I was thinking that it showed a particular high
resonance (mechanical?) at that particular point
but that is what I want it to represent.
This only appeared when the antenna was relatively
resistive (60 ohms) and 2Kc wide (resonated loop ala filter)
and applying max number of pulses per sectiom.
(professional program that provides high pulse useage)
At the moment I am trying to remove these small waves
by adding resistance to broaden the bandwidth.
Sorry the question is not as high tech as the present
flood of wave reflection, conjugate match postings e.t.c.
but it does provide something that all can voice an
opinion on and rejoin the group, hopefully after a little
bit of thought or a rummage thru a book.
Regards
Art

ok, you've done a nice job of copying the text you sent me.

They also mention that the normalized load impedance Zn=Zr/Zo does
NOT have the same angle as Zr because Zo is complex in the general
case.

> "They anticipate people being concerned about |Gamma| > 1 and later come up
> with a formula for time average power."

Really? Could you tell us more about that? Could you email me
more pages, especially the one that has Eq. 5.2b?

When it is incorrectly used. When you use a complex Zo
for a formula that assumes purely real Zo.

http://www.zzmatch.com/lcn.html

> This appears to imply that reflected power is greater
> than incident; something that would violate various
> conservation of energy laws.
>

for a lossless, passive network:

[s11]**2 + [s21]**2 = 1

If the sum of the squares is less than one,
there are losses in the network. Some people
might understand why this cannot be greater than 1.

> Dr Slick has therefore rejected the generally accepted
> formula and produced one which does not result in
> more power being reflected than is incident, thus
> satisfying various conservation of energy laws.
>

I didn't "produce" it or "make it up", the conjugate
equation is in the established literature (Kurokawa, Besser,
and the ARRL). But because Zo is usually assumed to be
purely real, most people know the "normal" equation.

> Many people took issue with this redefinition of rho
> and attempted to show why the generally accepted formula
> is correct.
>

The generally accepted "normal" formula IS correct, as long
as Zo is purely real. No disagreements there!

> But that does not address the issue with the generally
> accepted formula; how can reflected power be greater
> than incident?
>

Only with an ACTIVE network. Never with a passive one.

The "normal" formula concerns passive networks.

> A clear explanation of why rho greater than one
> does not violate conservation of energy would seem

>
> ...Keith

Incorrect. I am convinced that when you use a complex
Zo with the normal equation, you are using the formula incorrectly.

Therefore, there is no need to show why your answer doesn't
violate conservation of energy if your answer is wrong in the first
place!

"gasp!" ...saved by a lifesaver of logic while drowning
in the Sea of Ignorance!

Thank you Bill. This is probably why they say that
an oscillator has negative resistance (postitive feedback),
and also why the stability circles have their centers located
outside the unit 1 Radius. Clearly, areas outside the
rho=1 circle on the Smith, are reserved for active networks.

Para el Hombre Malo,
I don't think there's any panacea solution to your problem but the passive antenna should help with your cell phone. Just have the inside antenna close to where you'll usually talk and the outside antenna high and in the clear. For your other questions, I'm sorry but I chuckled a little. I couldn't tell if you were serious at first but then figured that you're not a licensed ham radio operator.
Active repeaters: yes, often very expensive, Code of Federal Regulation legal issues and FCC licensure.
"All frequencies all the time": not realistically, I think it's called a transponder used on a communications satellite but on steroids.
Building codes require that your house be grounded. It's grounded unless you built it yourself and forgot to do it:)
Alot of things can affect your radio reception and to pursue all of them for a radio station is to joust windmills. Just make sure your connections are good. I wouldn't drag chains behind your truck because they attract bicycles and electric wheelchairs. Your truck is all the "ground plane" for your antenna. As for a radio at work, just pick up a simple antenna from radio shack if it's AM/FM. They're made for your application so it doesn't get much better or simpler.
You might consider looking up a ham radio club in your local area. They might have licensing classes where could learn about all of these issues and much more. If you're interested, a lot of "Old Men" (respectful term of address between hams) are willing to help you learn and improve radio communication skills. When it's said and done, you've earned your license for free. Give it a try if the idea strikes you.
"73" comes from old radio operator brevity codes that were used to send a common question or statement as short and easy as possible. I believe it meant, "Warmest Regards" or something to that effect since it's understood outside of language barriers. So, that's the way we commonly sign off.

73's y un saludo muy cordial pa' ti y los suyos,

Hi OM,

This does not follow logically. Active networks exhibit this behavior and offer a library full of applications. Strained passive networks, as evidenced by other correspondence, also reside in this "forbidden region" but their number are significantly smaller and for good reason.

Those examples were "strained" for the purpose of your education and rarely offer engineering coupes of design. More often they represent the "gotcha's" of technical oversight and unplanned failure modes. As such these side-bars offer insight, but hardly have the horsepower to pull the load.

Both sides of the debate can whip that horse, but it ain't moving another inch for anyone.

As for a horse of a different color, how well tutored are you to handle specifying the loss in a system of two resistors and a hank of line? (Line loss is the characteristic being sought.) No prizes are offered, but you have and excellent prospect of beating the experts to the crossing line.

It's as simple as giving even an incorrect answer! :-)

As the rich and powerful offer, the better part of success is just in showing up.

Hi Jim,

You can look at the history of any web site by going to
http://www.archive.org and look back through time to see how their web
page has changed. For example, look at:

http://web.archive.org/web/*/http://cushcraft.com

I looked through the Cushcraft web site content between Mar 29, 1997 and
Jun 02, 2002, and while the site has changed in looks, they really
didn't do much for content until recently. I couldn't find a thing
about the R3 antenna.

But at least you might be able to use this as a reference for other
"ancient" (pre-2000) hardware.

All the best, and 73,
Dave

I am trying to salvage the situation before going to
war with Antennas and More with my credit card company. They shipped the
wrong antenna to me and have NOT answered numerous calls or emails. I was
looking for a 40 meter OCF dipole and they sent me a 80 meter OCF, which
was not what I ordered because of space limitations.
If I could cut the thing down to use on 40 meters then I can save the
inevitable hassle of dealing with this outfit and going to war with them via
my credit card company.. However, my understanding is that a lot of the
commercial builders of the OCF dipoles use a 2/1 balun for their 40 meter
antennas since they are trying to match a different impedance spot on the
shorter antenna., hence it is not necessarily the case that you can just cut
them down. Any thoughts?

> one, is reserved for active networks only.

Stable amplifiers also reside inside the Smith chart. When their gain circles overlap into the outside they are "potentially" unstable and need to have networks designed that keep them from becoming unstable, by confining their operating point to the inside. When the gain circles are entirely outside the chart they are definitely unstable. Oscillators are designed to have their gain circles in this manner.

Passive linear bilateral networks do not oscillate. An active negative resistance device or a positive feedback amplifier is needed.

An amplifier consists of three things:

1) A matching network at the input that transforms impedances.

2) An amplifying device such as a transistor that has a forward gain.

3) A matching network at the output.

The matching networks are designed to produce gain and stability.

I've never actually seen the voltage at a node in a standing wave pattern referred to as an instantaneous voltage - especially considering that it doesn't vary with time. Instantaneous usually means the solution to a function f(t) at time t (not f(x) and position x.) Nodes and zero crossings aren't necessarily the same thing.

Yes indeed. And since this happens when the impedance
increases, energy can be conserved.

But the discussion was about reflected voltage and how using
the generally accepted formula can result in the reflected
voltage exceeding the incident voltage. Converting this
voltage to power would result in a greater reflected power
than incident which would seem to violate conservation of
energy. Perhaps this would be an interesting place for
you to apply your energy analysis?

Why not just scale the antenna? That's is to say, in your case, reduce
the length of the wires by a factor of ï¿½.

Source record: 109277

Group:

Another very good and inexpensive reference on waves that might be of interest to this group is:

William C. Elmore and Mark A Heald, "Physics of Waves", first published in 1969, but
most recently published in paperback by Dover Publications, New York, 1985 and
generally available in reprints even today for around US$17.00. A real bargain.
ISBN: 0-486-64926-1 LCCN: 85-10419.

Be aware, since this is a Physics book it is loaded with gratuitous partial differential
equations.

This book is interesting because it covers the *whole* field of waves, not just
electromagnetic waves.

Electromagnetic waves are particularly simple when compared to general wave phenomena,
since em waves are transverse only.

This book covers waves on strings and membranes, waves in and on fluids, waves in compressible
media such as the earth [the seismic wavefield]etc... and so covers many of the "analogies" that
posters to this news group like to draw upon, often drawing false conclusions.

Are ocean waves at the beach *really* analogous to em waves?

This book will explain why not.

The earth supports both transverse and compressive-dillutive waves as well as surface seismic waves. Are compressive-dillutive waves different either qualitatively or quantitatively from electromagnetic transverse waves, this book answers the question.

etc, etc...

Expand your wave horizons beyond mere em waves, if you are deeply interested in waves, this book is more than worth the price at US$17.00. It's available from Amazon.

I thought this was only true for waves moving through a lossless medium or in a lossless transmission line that supports TEM waves. Either the electric or magnetic field isn't transverse in a hollow waveguide, and either or both can be non-transverse in a lossy medium.

Or am I mistaken about this?

[snip]

Dave you are being picayune. No one wins a pissing contest like this,
everyone just gets piss on their hands.

I could respond with... OK then... how about a transmission line of length
somewhat less than exp(-exp(-exp-1000))) meters in series with a 1 Ohm
resistor. Will that do? Or do I could use a "recursive" definition.

It simply doesn't address or affect the point at hand, which is that a
complex Zo line terminated in its' conjugate will exhibit a non-zero
reflected voltage. Do you agree? If not, what 's your point?

"When I use a word", Humpty Dumpty said, in a rather scornful tone,
"it means just what I choose it to mean, neither more nor less."

"The question is", said Alice, "whether you can make words mean so many
different things."

"The question is", said Humpty Dumpty, "Who is to be master: - that's all."

-- Lewis Carol, "Alice in Wonderland - The Turtle soup"

Dave, I am willing to help you understand my unimportant proof, I didn't
realize it was such a big
deal, but hey... I recall you asked or commented about my posting, but if
all you wanted is to fuss
with me over side issues such as if lumped systems obey different laws than
distributed systems, then
I presume that we will have to agree that we cannot have a productive
discussion..

If I have offended you in some way, I did not mean to, please accept my
appologies.

Best Regards,

> 73, Cecil, W5DXP

Cecil,

I actually did a test along these lines. Believe we discussed that some
weeks ago before I did it.

1/4 wave 50 Ohm line shorted at the end. Freq ~ 2 MHz

50 Ohm generator in series with a 75 ohm resistor at the other end.

Looked at both ends of the 75 Ohms, both to ground, and differential.

At resonance, all voltages were in phase.

Unfortunately I used very low loss line, but to a good approximatio, the
only power supplied by the source could be explained by cable loss, and all
reflected power was re reflected. It would be interesting to do this with a
total source impedance of <50.

BTW, I also did the thing with measuring VSWR and then changing the source
impedance. Power changed, VSWR did not, for either 1:1 or 1.7:1.

From: Jo=?ISO-8859-1?B?4w==?=o Paulo Carvalho <jvaz.carvalho@netcabo.pt>
Message-ID: <BB75B3DC.9C7%jvaz.carvalho@netcabo.pt>
Source record: 109286

Hello everybody.

I want to set up an antenna in my new home and I'm searching for suggestions on how to do it.

I have a large balcony in the corner top floor of the building. The north and west side of the balcony are facing the street and on the south and east of it there are walls that go up to the roof. The higher point of the wall is about 5,5 meters tall. I want to set up a vertical antenna with nearly 5 meters tall and weights about 10 kilograms.

I thing the best thing to do would be attaching a mast to the higher wall and the antenna on the top but I don't know if it's the best.

Can someone give a suggestion?

Thank you all.

4543. DXCC Qsl cards ?

I finally have 100 countries.
But some are older than 10 years. Does this present a problem?

What bands are valid for DXCC?

What are some common reasons cards get rejected?

If they don't count all 100 and reject them... will they give
credit for the ones they did count?

Do WARC bands count?

[snip]

Compressive-dillutive waves occur only in media that is compressible, like the earth or the air, or springs, etc... With compressive-dillutive waves the "vibrations" occur in the effective density of the medium.

Electromagnetic waves propagate with transversal vibrations of the E and H fields, viz. Side to side vibrations, not shortening and lenghtening vibrations. If an electromagnetic wave is supported in the Transverse Electromagnetic or TEM mode then [theoretically] the E and H fields are at right angles to each other and to the direction of propagation, in the terminology of TEM, the term transverse referes to the orientation of the wave with respect to it's guides, and not to it's vibration mode in the longitudinal - transverse sense.

Visualize a long "slinky" coil attached to the wall. Shake one end up and down to create a transverse wave in which the slinky moves up and down. Push and pull on the end to produce compression and dilution to cause longitudinal waves in which the slinky does not move up and down but in which the distance between turns moves back and forth. This slinky analogy sort of illustrates the differences. Meanwhile in electromagnetic wave phenomena you have as well as the most common TEM mode which is only transverse vibrations, also there exists a plethora of TM and/or TE modes, or even in the near field, where the fields may not be at right angles to each other or to the direction of propagation, but the vibrations are still talways transverse, i.e. not compressive-dilutive.

Back in the mid-1800's after Maxwell produced his celebrated equations and Heaviside improved them by expressing them in vector form most scientists of the time noted that Maxwell's formulation provided no explicit form for a medium for the electromagnetic waves to propagate in, and they also noted that there were only transverse and not longitudinal [compressive-dilutive] vibrations supported by his equations. Several eminent scientists of the day felt that this left openings for several more discoveries and so... Then ensued for several decades a search for the "ether". The "ether" was

supposed to be the media which supported the electromagnetic waves. During that period several of the eminent scientists of the time proposed that the "ether" once it was found might actually be compressible and they proposed that Maxwell and Heaviside had left out of their formulations the possibility of compressive-dilutive or longitudinal vibrations. Several scientists of the time actually formulated equations which supported compressive-dilutive em waves and actually conconcted and, to no avail, actually conducted experiments to try to find out if such compressive-dilutive vibrations actually occured with electromagnetic phenomena.

As we all know, eventually the existence of the "ether" was discredited, mainly by the Michelson-Morley experiments, and today we all know that electromagnetic waves do not have a media or "ether" to support their propagation and vibrations.

Electromagnetic waves propagate just fine in a complete vacuum, and a vacuum is incompressible, and so the search for compressive-dilutive vibrations of electromagnetic waves became moot and a search for experimental evidence of them was abandoned by all who were interested. One can add terms to the Maxwell-Heaviside equations to support compressive waves, and this has been done by several theoretical physicists, but there is no sense doing so since none have ever been discovered!

The book, I referred to above, "Physics of Waves" gives all the details of the wave equation for media that supports compressive waves. An important such field is the field of seismology. Indeed the field of siesmology studies waves that vibrate in all modes, transversally and longitudinally, as well as surface waves. Seismic waves are processed regularly with beam forming arrays of seismometers and processed by tomographic techniques to image the earth in all wave modes.

Seismology is a facinating field and seismologists are generally the most sophisticated of all wave mechaics!

A good modern book on the seismic wavefield is:

B. L. N. Kennett, "The Siesmic Wavefield", Cambridge University Press, New York, NY, 2001. ISBN: 0-521-00663-5.

But be aware it is full of gratuitous partial differential equations and tensor analysis. The stress-strain variables of compressible-dillutive media are expressed as tensors and the partial differential equations are cast in tensor form.

All this to say that electromagnetic wave phenomena are a particularly simple form of wave phenomena when compared to the most complicated types.

This is proof that the Californian artist Garvin Yee, who styles himself as a doctor and yet is not in the amateur radio data base, does not know what he is talking about. He may well be just a "troll."
It is indeed a well know fact that best NF and maximum gain are not expected to coincide. Those of you who have been reading the group for a while will remember my story about proving this to Prof Kraus when I was his student.
Mr. Yee should play somewhere else.

One thing that as always bothered me is that antenna is not balanced
with that lop-sided feed. Further-the-more that assumed 300-Ohm
impedance has a pretty hefty reactive component. As baluns like
resistive loads I would question just how well the balun works under
that condition?

I too have modeled the antenna and agree that the claims made
regarding feedline's radiation contributing to a strong vertical
component is over stated to say the least.

Good luck with your cut and try.

4553. WTB: Cliff Dweller Rotatable Dipoe Centre Antenna Section

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-30 02:48:54 UTC
From: Norm VE3CZI <ve3czi@arrl.net>
Message-ID: <qpU3b.3961$Pa1.177316@read1.cgocable.net>
Source record: 109297
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.boatanchors,rec.radio.amateur.homebrew,rec.radio.swap

I have the End Coils & Control Box for the Cliff Dweller Antenna that was
Mfd in 1960's by New-Tronics.
The Model was CD-40-75. It was essentially a 40 & 75 Meter Rotatable
Dipole.
I need the centre Motor Assy and extended 10 ft extentions between the
Center Motor Assy and the End 40/75 Meter Coild Assy.
I got the parts I got from an Estate Sale, but the widow did not know
anything about a Centre Section...I have done some digging and have info
from Newtronics but is limited.
Any assistance would be appreciated...even close up pictures of the centre
section so I "may" be able to fabricate a similar assy would be appreciated
Thank You for your time....Norm

Thanks for the most interesting discussion of slinkys, "ether", and seismology. But I'm a little vague on what you mean by "vibrations". You're describing a field whose orientation isn't necessarily at a right angle (transverse) to the direction of propagation (as in a TE or TM mode wave), yet whose "vibrations" are nevertheless at a right angle to the direction of propagation. So the "vibrations" are in a different direction than the field. I'd like to learn more about this phenomenon, but I can't find "vibrations" in the indexes of any of my electromagnetics texts. Do they have another name?

Agreed. This makes sense, as when outside the rho=1
circle, the reflection coefficient is greater than one,
which implies positive feedback.

From: carter <cartw@netart.com>
Message-ID: <3F5022DB.84E55202@netart.com>
Source record: 109308

I'm sending in for the regular DXCC and a few things are unclear
to me:

1) Would a CY9AA (St. Paul Island) from 1997 on 160 meters
count?
Thought I read somewhere that 160 meters doesn't count on
the regular DXCC.

2) I have a 3E1DX from Panama. But on the list it doesn't
have 3E1 for Panama listed. Only HO-HP#* is listed for
Panama. It was a CQWW contest in 1997. Am I out of luck?

3) Have a 4N7DW from Yugoslavia from 1993. Once again
this prefix isn't listed on the ARRL list for Yugo (YT prefix is)
Out of luck??

4) I have a Pitcairn Island VR6BB from 1993. VP6 is now
listed as being Pircairn Island. VR is now Hong Kong.
What gives with this one??

5) I have a HA5-350 from Hungary from 1996. Not allowed?

Antennas are scalable so halve the length of the antenna while keeping the
ratio of short leg to long leg the same. Depending on the design, you may
also have to halve the length of the feedline to exactly duplicate 75m
performance on 40m. Hopefully not since 1/2WL on 3.5MHz is about 1WL on 7.0MHz.

Hi,

I am working with some 2.4Ghz panels for wireless antenna.

I am trying to find a suitable rotor for a RV. I only need the mast to be 4 feet high, but I need to be able to raise/lower the mast. And once the mast is raised, rotate it.

Anyone suggest a solution / product?

Thank you.

Hi Cecil,

I have no idea what you can assume. You generally express it freely
anyway.

> How do you measure the exact amount of
>reflected power re-reflected from the source?

Dan's spreadsheet work seems like a good place to start. It is of no
particular interest to me and doesn't respond to the challenge in and
of itself. You might find an exact answer there. Simply going to the
bench would be adequate for amateurs, guessing would eclipse the
efforts of everyone else. ;-)

It should seem obvious that the power reflected at the source
interface is governed by the standard mechanics no one wishes to
impart to the source. In other words the power returning to the
source will be reflected through the same mechanics it met at the
mismatched load, with the "exact" value varying only by the reflection
coefficient of the source mismatch and the power incident upon it. As
the line presents a media of 50 Ohms, and the source presents a 100
Ohm discontinuity, the portion of power reflected is a rather trivial
computation - except for those who apparently employ "first
principles" in one direction only. Gad, I love that bit of irony!
And they do it for the sake of educating lurkers too!

Hi Ian, George, you will find this in chapter 9 from Chipman (got it
right that time George ;-). It also accounts for the increased loss
exhibited by the example of the Challenge that so baffles everyone. I
wonder what those so bench-shy would attribute that additional loss
to? Would their astrologers suggest the opposition of Mars? Hint:
the answer works at all aspects of any planets.

For those who closely follow their astrologer's advice, I once again suggest this only matters to those interested in accuracy. With equipment available across the counter in exchange for a credit card charge, their purchase is not likely to suffer any issues brought to the forum here and they can rest assured their SWR meters will work as advertised given the likely source Z of being 50 Ohms or insignificantly off from that value. (Many will gladly suffer 2:1 mismatch straight from the antenna connector so they can worry it at the antenna.) Further, for inferior purchases at similar cost (how would they know?), they will still be unaware barring some change in the length of cabling that will have them muttering a moment or two before they shrug it off anyway.

I believe you have specified more numbers than you can actually know. In
particular, the forward and readings from the so-called "directional
power meter" will be totally dependent on whichever version of
transmission-line theory you're about to apply to the problem.

Therefore this particular thread of discussion is doomed :-)

I think not. Standing waves are spatial. At certain points
on the line the (NET) voltage is always zero: nodes.
At other points on the line, the (NET) voltage is sinusoidal
and has 2 zero crossings per cycle. The amplitude of these
sinusoids varies spatially along the line resulting in the
standing wave.

In an ideal line terminated by Zo, no matter where you attach
your oscillograph to the line, you will observe a sinusoid
of the same amplitude. This sinusoid will have zero crossings
and power at the time of these zero crossings will be zero;
no energy will be flowing at the time of the zero crossing.

And going back to the comment that started this sub-thread,
it is this cyclical variation in energy flow which prompted
the power dudes to invent three phase lines in which the
energy flow does not vary cyclically; power is constant.

While the standing wave will be difficulty to observe, none of
the equations related to ideal transmission lines require a
minimum length. The reflected voltage and power can be trivially
calculated just as it is for RF. Let me do it for you.

120 Volt RMS line, open circuit, assume 100 Ohms for the lamp cord:
Vf = 60V RMS, Vr = 60 V RMS
Pf = 36 W, Pr = 36 W

Unfortunately, such a situation only occurs when the line is in
steady-state which means no information could be sent, which would
render the line economically unviable.

Don't need to measure phase shift to obtain forward and reflected
voltages and powers.

But I think I understand the technique. Whenever the theory would
produce answers with which you might be uncomfortable, rather than
producing those anwsers and attaining a better understanding of the
viability of the theory, you prune the problem space to which the
theory applies. Ergo, not for DC, not for 60 Hz, not for lamp cords,
not for step functions. But the math from the theory works just fine
in all these situations. Try it.

> energy to be flowing in both directions.

This does seem to be the sticking point, doesn't it. Starting with
p = v * i,
i = charge_moved/time,
if no charge moves, there can be no power, and from
p = work/time,
if there is no power, no work is being done,
and if no work is being done, no energy has moved.
Ergo, no energy crosses the boundary.

If you find an error in the above derivation, I will happily allow
you that energy flows in both directions.

> Two waves flowing in opposite
> directions in a constant Z0 environment superpose but have no effect
> on each other. You are continuing to be confused by the NET values.

Actually, I am not confused by NET at all. I contend that NET is the
only thing of importance when determining if energy flows.

> Did you take a look at that Java-driven web page that I posted a couple
> of days ago. If so, I don't see how you could still be confused.

Are you referring to
http://www.mellesgriot.com/products/optics/oc_2_1.htm?

These dudes do seem to have it right. They sum amplitudes to get
the resultant (NET) amplitude and then compute the intensity (power)
from the resultant (NET) amplitude. They do NOT state that energy
flows across a point with zero resultant amplitude nor do they sum
the power (intensity) to determine interference patterns.

> As an analogy, consider two equal magnitude Tsunami waves flowing in
> opposite directions in the ocean. According to you, these waves will
> reflect off of each other. But it is known that those two waves will
> simply flow through each other and continue their original paths
> unabated.

How can you tell whether it reflected, or flowed through?
The look and feel will be the same.

Remember the collision of two identical balls. Superficial examination of the collision might cause one to conclude that the energy was transferred between the balls, especially if you viewed this collision after viewing the collision of a moving ball with a stationary one where energy is indeed transferred. Only by looking at the details of the collision, in particular at the interface where the collision occurs,
and realizing that f * d is always 0 do you learn that no energy was transferred.

Similarly for transmission lines at points where v(t) * i(t) is always 0 and, from the web page, apparently for light as well.

We did, but with having to create and run over 100 EZNEC models, document same in a 40+ page technical write-up, do two other technical write-ups, plan the BPL field-trial testing, do the BPL field-trial testing, all on the fastest fuse I have ever seen the FCC put a major issue on, it was inevitable that small errors crept in. Every single publication I know, ARRL or other, contains errors. The fumble-fingered typing of 115 where 135 was intended is just not something that would have been caught in a proofreader's read.

> If a physical impedance discontinuity exists, then of course, the flow of
> energy in the individual waves is affected by reflections.

The statement "in the absence of an impedance discontinuity there are
no reflections" is an oft made assertion which deserves some scrutiny.
Some time back Cecil provided an example which sparked some thinking:

"For instance, in the following two-port network:

source---50 ohm feedline---+---1/2WL 150 ohm feedline---50 ohm load
<snip>
Since a Z0-match exists at '+', the reflection coefficient on the
50 ohm feedline is zero. rho = Sqrt(Pref/Pfwd)"

Temporarily view everything to the right of the "+" as a black box.
When we measure its sinusoidal steady state impedance we obtain a
value of 50 ohms. Connect it to a 50 ohm line, rho is 0 (as
mentioned above) and there are no reflections.

When we open the black box, we find that there is 150 ohm line inside,
rho should be 0.5 and there should be a reflection. (And there isn't,
of course, because the multiple time domain reflections sum to produce
the final steady state reflection of 0).

We have a choice of two rho for this situation:
black box - 0, computed from the surge impedance of the line and
the steady state impedance of the load
open box - 0.5, computed from the surge impedance of the line and
the surge impedance of the load

Since the terminologies are similar, great care must be taken in
discussion to distinguish these two cases, as evidenced in another
thread where a discussion on conjugate matching is being confused
by exactly this.

In any case, what we have in this experiment is a case where there
IS an impedance discontinuity and yet there is no reflection (if
you use the "black box" rho, as is often done).

This, or course, sparks the symmetry question: Can there be a
reflection when there is no impedance discontinuity?

Consider another black box. Measuring the steady state impedance
results in 0. When this black box is attached to a 50 ohm line,
rho is -1 and all of the incident voltage is reflected.

But when we pop the lid, we discover the box consists of a quarter
wave of 50 ohm line terminated in an open circuit.

Similar to the first experiment, and not surprising, there are two
rho available:
black box - -1, computed from the surge impedance of the line and
the steady state impedance of the load
open box - 0, computed from the surge impedance of the line and
the surge impedance of the load

So, if we are allowed to say in the first experiment that rho is 0
despite an impedance discontinuity, we are equally allowed to say
for the second that rho is -1 despite the absence of a discontinuity.

This, quite reasonably, allows us to imagine an interface at any point
in the line (not just at discontinuities) and, knowing the steady
state impedance on the load side of the interface, compute the rho
which will describe the steady state reflection on the generator
side of the interface.

Of course, when not dealing with sinusoidal steady state approximations,
(that is, when dealing in the time domain), only the rho computed from
the surge impedances will be of value.

There was no actual power generated by the source. Some people seem to think that *power* dissipated by the resistor due to current flowing in one direction and *power* caused by current in the other direction cancel. Of course, the experiment was moot, or 1/4 wave stubs wouldn't work. Ghosts live in the realm of pulses, where things always work unambiguously. In logic design, you often terminate the source, so there is only one reflection. You can't series terminate the load, because the input impedance is several K; you can't shunt terminate the load because the source can't deliver enough current, although I have done things like shunt terminating the load with a Zo resistor in series with 10PF or so.

[snip]

Vibrations = oscillations

An instance where compressional-dilative waves might occur in electromagnetic propagation and where those compressional vibrations terms could be added to the Maxwell-Heaviside equations might be that of electromagnetic propagation through "light ion" plasmas [ionized gases] where the ions could physically respond essentially instantaeously to the passing waves and the distance between ions and hence the media properties becomes a function of the electromagnetic fields. The effective mu and epsilon of the media changing instantaneously in response to the propagating fields, in turn changing the waves, etc... just as for compression acoustic wave propagating in a compressible gas. This effect is probably infinitesimal for "heavy ion" plasmas and might be perceptable for "light ion" plasmas. I wonder if any readers of this NG have any experience with propagation in plasmas and can share with us if they use compression-dilutive terms to augment the Maxwell-Heaviside equations in the analysis.

I presume that the NEC code that you use in EZNEC to integrate the Maxwellian equations does not support plasma propagation analysis. Perhaps someone knows of a version of NEC that does. I'd guess that folks at Lawrence Livermore and at NASA are interested in such problems. I'd be curious to know if they use augmented versions of Maxwell-Heaviside equations.

Another, arcane, far fetched, and impractical example of compressional-dillutive vibrations in em waves that I can think of could be imagined as a system wherein em waves travel in a waveguide system where the

dimensions of the system [walls of the waveguide] are such that they can move in and out instantaneously in response to the passing waves thus alternately confining and expanding the dimensions of the guide relative to the wavelength of the passing waves, it might be imagined that such action could induce a wave shortening and lengthening effect on the passing waves which is what compression-dillution waves are.

Thoughts, comments?

Say did you order your copy of "Entanglement" yet?

You will really enjoy that book, a great read about all of the progress in QED physics throughout the nineties, and the attempts and successes of the modern generation of theoretical and experimental physicists at answering Einstein's objections to instantaneous action at a distance.

Although dated, and not up to date with the latest laboratory experiments and theoretical developments on entanglement, another great layman's introduction to QED is Feynman's book named simply "QED". It is a sort of laymans explanation of QED by Feynman himself which parallels his more detailed and mathematical development of QED in "The Feynman Lectures on Physics", but without all the math. I think Feynman's "QED" is still in print in paperback. I have a copy, but I saw in on the rack at Barnes and Noble a few weeks ago.

As you know every quantum, including bigger chunks of matter such as yourself has an inherent frequency associated with it, and so from time to time I have often wondered...

What is Cecil's wavelength and can I get on it?

;-)

I have done side by side comparison of a 102" whip tuned by an AH-4 equivalent vs. a resonant style antenna such as the Hustler series. On 40m, There was a repeatable 1 "S"unit difference in rx signal and tx signal strength. I did not have the chance to check it on other bands, but the difference would probably decrease as you got closer to 10m, and increase as you went to 75/80m

Bottom line is that if you want/need performance in a mobile environ, use some sort of resonant antenna, especially on the lower bands. However, a 102" whip will do for convenience. Or you can split the difference and get a screw-driver style antenna.

I have not built them, just followed discussions, mostly on TopBand reflector.
K6SE and other exchanged lot of information.
The soil conductivity impact would be as with verticals (it is in a sense
phased verticals), good soil will enhance low angle, stretch the lobe down to
horizon. Important thing is to use baluns on the coax to maintain max clean
pattern to eliminate effect of feedline for good rejection.
Check TopBand reflector archives, I you have not seen them.

If you are going to tune radials, they have to be above ground
level by a distance that makes setting up a vertical a much more
complex matter. The idea of tuned radials allows you to operate with
as few as three and provide an effective rf balance for the antenna.
The main idea of the radials, tuned or untuned is an rf ground to
act as the phantom half of the vertical. They need not be tuned, but
if you lay them on or below the ground you need more of them. On the
ground, what would have been a tuned radial, interacts with the soil and
detunes, so the length becomes unimportant. You provide the ground by
using more radials of various lengths, and they need not be spread out
as 'radially' as the pictures show -- but the more the merrier, and the
more effective they will be.

One of my verticals was four feet from the house. I fired an arrow
into the air, so to speak, but my arrows (signals) landed into a lot
of very interesting places (other stations).

Some lucky guys have their verticals mounted right at a tree and use
it for the vertical support.

Hope this is clearer than mud :-)

Looks like SWL card? If not, then no problem.

From time to time some countries use special prefixes that are allocated to
that country. As long as the station is on land and in particular country,
there is no problem. Only some operations - DXpeditions that did not provide
proper documentation, would not be credited.

Yuri

160 Meters counts as we told u before. Please see URL:
http://www.arrl.org/awards/#dxcc
sez
The premier operating award in all of Amateur Radio is the DX Century Club. The basic certificate (which can be obtained in several categories--Mixed modes, Phone, CW, RTTY, Satellite, 160, 80, 40, 30, 20, 17, 15, 12, 10, 6 and 2 meters) is awarded for working and confirming at least 100 entities on the ARRL DXCC List.

> 2) I have a 3E1DX from Panama. But on the list it doesn't
> have 3E1 for Panama listed. Only HO-HP#* is listed for
> Panama. It was a CQWW contest in 1997. Am I out of luck?

Many countries have a primary and a secondary prefix (the later often used for contests and special events).
In general, the ARRL DXCC list has primary prefixes not secondary. - The complete prefix allocations can be found at
URL: http://www.arrl.org/awards/dxcc/itucalls.html
Or
http://ac6v.com/prefixes.htm

There u will see that Panama prefixes are HOA-HPZ Panama (Republic of)
(Also See H3, H8, H9, 3EA-3FZ)
So it is a good Prefix and contact

>
> 3) Have a 4N7DW from Yugoslavia from 1993. Once again

In general, the ARRL DXCC list has primary prefixes not secondary. - The complete prefix allocations can be found at
URL: http://www.arrl.org/awards/dxcc/itucalls.html
Or
http://ac6v.com/prefixes.htm
4NA-4OZ Yugoslavia (Federal Republic of) (also See YT-YU , YZ)

Should count as Yugoslavia

>
> 4) I have a Pitcairn Island VR6BB from 1993. VP6 is now
> listed as being Pircairn Island. VR is now Hong Kong.
> What gives with this one??
VR6 WAS Pitcairn - Now VR is China-- VP6 is the new Pitcairn Is Prefix Hong Kong was a British colony for many years --- but became the Hong Kong Special Administrative Region (SAR) of China on 1 July 1997. So they changed prefixes at about that time.
Now VRA-VRZ China (People's Republic of) -Hong Kong and VP6=Pitcarin
Pitcarin prefix got caught up in the change.

> ---

> 5) I have a HA5-350 from Hungary from 1996. Not allowed?
Sounds like a SWL card -- submit it anyway -- the DX desk allow or disallow it.

Danny:
I think the you have raised a valid concern about the
balun. This is something I did not fully appreciate before I made my
decision to try this. Cebik makes the same point and suggests if you use
this antenna you might be better off using a parallel feed line with a
tuner, and no balun. I will make the cuts and scale this antenna down
preserving the same ratio of offset. Before I hang this permanently I will
need to get a better feel for its performance and limitations. I may do a
head to head test with another antenna set up and see. I was intrigued by
W5DXP's "completed inverted L", which is a full wave loop variant.
The major benefit of this whole experience for me has been the amount of
research it has instigated. I also have a better understanding of antenna
options. I have come to the following conclusions about commercial
"windoms".(which really are folded OCF dipole antennas).

1. The claims about performance are probably overblown due to:
a. Faulty assumptions about the degree the "vertical
radiation" of the feedline plays in modifying performance.
b. These incorrect assumptions being placed into antenna
simulation programs and printed as truth.
c. Placebo effect: I suspect some of the testimonials
are due to expecting better performance. On some occassions the
improvement may actually be due to hanging these antennas at "recommended
heights". Of course your dipole would do better up there too.
2. The unbalanced feedline makes RF in the shack a common problem since
your "vertical radiator" can be coming into your shack, depending upon
whether you have taken the necessary precautions to prevent this.
3. You are almost always better off making your own antenna.
4. I do NOT recommend dealing with any amateur supply company that
routinely will not return inquiry calls.
5. Read up on OCF dipoles as much as possible before building or buying
one.

I will keep you informed of my
progress. I have truly appreciated the input. I hope this discussion helps
some other hams who are contemplating purchasing commercially made
"Windoms."

I'm ready to go to the bench but I don't know how to separate the
incident reflected power that is re-reflected from the source from
the generated power. That's what I am asking. How does one separate
those two coherent superposed forward waves?

> It should seem obvious that the power reflected at the source
> interface is governed by the standard mechanics no one wishes to
> impart to the source.

I agree that the source obeys the wave reflection model rules. The
fly in the ointment is the unknowable source impedance encountered
by the incident reflected waves.

> In other words the power returning to the
> source will be reflected through the same mechanics it met at the

I must have missed how you know the source presents a 100 ohm impedance
to incident reflected waves. Do you have a 100 ohm pad between the
transmitter output and the transmission line?

That's the whole point, Ian. Exactly how are those things knowable
if they give identical readings? I could argue that either of those
conditions exist and you cannot prove otherwise. There are probably
an infinite number of configurations that will yield identical
measurements. What I don't understand is how any of them can be
knowable.

For the infinite number of times a snapshot of the voltage is
not zero, the node *IS* a zero-crossing point. That is more than
obvious from the JAVA applets on this web page.

http://www.gmi.edu/~drussell/Demos/superposition/superposition.html#standing

> In an ideal line terminated by Zo, ...

That configuration is not covered by my statement above which
applies only to standing waves on lossless unterminated lines.

Rash assumption. Please prove that six feet of zip cord
exhibits a Z0 of 100 ohms to 60Hz signals.

> Of course, we were discussing sinusoidal steady state for which
> there will be no echoes. Echoes only happen when the line energy
> state is changing.

In reality, there is no such thing as sinusoidal steady-state
and noise in the system cannot be eliminated. The noise can
be used to prove that echoes (reflections) are still happening.
So nothing magic happens at sinusoidal steady-state. The wave
reflection model does NOT magically become dysfunctional at
steady-state.

> But the math from the theory works just fine
> in all these situations. Try it.

I know the math works *IF* you can define the boundary conditions.
Assuming that 50 ohm coax exhibits a Z0 of 50 ohms at 60 Hz is
a rash assumption.

There is no sticking point. It is all explained in _Fields_and_Waves_...
by Ramo, Whinnery, and Van Duzer. It is also explained in _Optics_,
by Hecht.

> If you find an error in the above derivation, I will happily allow
> you that energy flows in both directions.

That a forward Poynting vector and a reflected Poynting vector exists
is not enough for you? Here's my argument analogous to yours:

My GMC pickup is white. Until you can prove my GMC pickup is not white,
your argument is invalid. Your above argument is just as irrelevant
as the color of my pickup.

> Actually, I am not confused by NET at all. I contend that NET is the
> only thing of importance when determining if energy flows.

What about the forward Poynting vector and the reflected Poynting vector?
Net is the thing to consider if all you are worried about is net energy.
Net doesn't hack it when you take a look at the forward and reflected
Poynting vectors.

> How can you tell whether it reflected, or flowed through?
> The look and feel will be the same.

Not exactly. Each Tsunami has its own modulation signature. Many, many
experiments over hundreds of years have proved that waves flow right
through each other.

> Similarly for transmission lines at points where v(t) * i(t) is always
> 0 and, from the web page, apparently for light as well.

You really believe that the energy in a bright interference ring is
trapped between the dark rings by some magical force that exists in
your mind? You really need to read the superposition and interference

chapters in _Optics_.

Charles,

Looks like you've got a good handle on things. I have used an OFC, fed
with ladder line. Nothing particularly outstanding in its performance.
However, as to common mode current: running around 100 watts I
experienced no problems, but when I bumped up the power to about
600-watts all hell broke loose. My computer, the TV, stereo, touch
lights and just about any thing else electronic went wild. And I use a
pretty good single point RF ground system here. So be prepared that
some "strange things" may happen. <g>

Good luck, nice talking with you.

Actually, Sqrt(Pref/Pfwd), the definition of rho.

> open box - 0.5, computed from the surge impedance of the line and
> the surge impedance of the load

Actually, (150-50)/(150+50), the definition of s11.

> In any case, what we have in this experiment is a case where there
> IS an impedance discontinuity and yet there is no reflection (if
> you use the "black box" rho, as is often done).

This is technically not true. The NET reflections are zero. There
are two non-zero component reflections as seen from the s-parameter
equation:

b1 = s11*a1 + s12*a2

These three terms are all reflections. b1 is the NET reflections
toward the source. Since b1 = zero, s11*a1 = -s12*a2, i.e. the two
component reflections are of equal magnitude and opposite phase and
therefore cancel. This is explained in the last three paragraphs on
the Melles-Griot web page.

> So, if we are allowed to say in the first experiment that rho is 0
> despite an impedance discontinuity, we are equally allowed to say
> for the second that rho is -1 despite the absence of a discontinuity.

There is NOT an absence of a discontinuity. The discontinuity is as
large as it can possibly be, an unterminated transmission line. There
is an infinite SWR on the 1/4WL line. The apparent zero impedance
at the input is simply a V/I ratio where Vnet=Vfwd+Vref=0
The forward wave is carrying Vfwd^2*Z0 watts associated with the
forward Poynting vector and the reflected wave is carrying Vref^2*Z0
watts associated with the reflected Poynting vector. A directional
wattmeter will indicate the same thing.

There is NO physical discontinuity at the black box. The only physical
discontinuity is the open end of the stub. That's where 100% of the
reflection action takes place.

As a matter of fact, it was measured on 75m. My 11.5' whip with an SGC-230
tuner was 12dB down from my top-loaded junk box antenna. That's two (or more)
S-units. A 9' whip would be even worse. Why spend all that money on a tuner
that dissipates 94% more power than a tuned 75m mobile antenna that costs
less than the tuner?

I'm trying to find a place (in the US) to purchase ferrite donuts so I can wind my own balum. Any recommendations?

Also, when looking at manufacturer's websites, there seems to be a selection of chemistry to their cores. Is there one formulation that I'm looking for in particulate?

Hey Cecil
I have both the AT180 and the AH4.
They're on a shelf.
In a closet.
I use a resonant Hustler with a toroidal matching transformer.
I want a screwdriver-type antenna.
73
H.
NQ5H

OB 706 comment: Good radio. Great audio.
Have one in the truck.

Nobody is using superposition for power. Do you deny the fact that
two 100W light bulbs put out more irradiance (power) than one?

You argue that there must be reflections at a voltage node. The
above web page indicates such doesn't exist. Those forward and
reflected waves flow smoothly right through each other. Take
another look.

> the Melles-Griot web page.

Yes, but only if the box is open. How do you analyze the black box
when you are only permitted to know the impedance at the inteface
looking
towards the load? rho is just computed from the only information
available. No one complains that the problem can't be solved.

> > So, if we are allowed to say in the first experiment that rho is 0
> > despite an impedance discontinuity, we are equally allowed to say
> > for the second that rho is -1 despite the absence of a discontinuity.
>
> There is NOT an absence of a discontinuity.

There is no discontinuity at the interface in question.

> There is NO physical discontinuity at the black box.

Exactly, and people argue that it is inappropriate to claim that a
reflection occurs at this interface.

And yet, in the symmetrical case where there IS a discontinuity,
many are quite comfortable talking about the lack of reflections
at the inteface.

So, if you don't wish to permit reflections at interfaces without
an impedance discontinuity, please never speak of an absence
of reflections at an interface with a discontinuity.

If it's good for the goose, it should be good for the gander.

Worry about it if the example of the challenge presents more than 3+
dB loss. If not, there's hardly any point is there? We can work out
the differences then, but only if you care about accuracy and the lack
of confirming this exotic characteristic. I can appreciate that this
is not everyone's interest.

Hi Cecil,

I didn't say I did the example, it is drawn from a reference. We've
already been through the mechanics of how to do it employing a
variable transmission line. Consult our correspondence for specific
details, you already offered that your equipment could tolerate that
mismatch, however THAT discussion is separate and distinct from the

example of the challenge. The challenge merely offers another approach. You can add a 50 Ohm Dummy Load in series to the output of your rig (this, of course presumes it presents 50 Ohms characteristic, but as many declaim that specification perhaps they could offer another value - eh, unlikely).

Another issue of adding a series resistor is one of shielding and common mode issues. You asked me in that earlier correspondence if I considered this, and yes I did. That is why I used massive parallel loads that insured an entirely shielded system. This is one of those methods that one correspondent pondered:
>>There is no institutionalized ignorance, just a
>>lot of skepticism regarding the reliability of the
>>analysis methods and the measurement methods.
which is understandable from those not trained in the art of designing measurement scenarios. I am trained but those still caught in the quandary are immobilized by rejecting every method (institutionalized ignorance). The measure of RF power is not simple by any means so it is best left to those who are serious about accuracy - hardly an amateur pursuit, and it hardly matters anyway as it is not a problem with modern equipment.

I offered that you already had the tools to perform a simple first pass approximation, you really need to consult that thread of correspondence again. None of this with forced mismatches is all that hard in the first place. The greater the mismatch at each end, the more compelling the evidence. The simple fact of the matter is that most rigs conform to 50 Ohm source Z and do not exhibit this issue. If those who held to their cherished fantasy of source Z being other than 50 Ohms, then they should be able to ace this test from the beginning (the lack of their correspondence reveals the invalidity of their claims).

I'm working on two repeater systems today (10M and GMRS), so enjoy.

The output rose to the open circuit value. Actually, I had thought of building a very efficient class C amplifier and calibrating the output power in terms of DC collector current, but think it is a waste of time.

hello to everyone,

I have a car antenne with 50 Ohm coax that I want to connect to an old radio with a 300 Ohm balanced input so I need a balun and impedance converter. Any info about how to build one will be welcome. (Being an amateur I don't want to buy one.)

> Nobody is using superposition for power.

It may have been my misinterpretation, but I understood you were
claiming that the net power distribution on the line should be
computed by summing Pf and Pr. If you weren't saying this,
then the other way to compute power is to use p(t) = v(t) * i(t) (NET)
which leads to no energy crossing the voltage and current zeroes.

> Do you deny the fact that two 100W light bulbs put out more
> irradiance (power) than one?

It is my policy never to deny facts. I leave that for others.

> You argue that there must be reflections at a voltage node.

No. Merely that if there were, the picture would be no different.

> The above web page indicates such doesn't exist.

Visualize the picture if there were reflections at the minima
and maxima. The plots would look exactly the same.
Curiousity -- why are you so sure there aren't? The picture
would be the same!

> Those forward and reflected waves flow smoothly right through
> each other.

Another way of viewing the picture and as long as you stick to
voltages and currents; no problem.

It is only with the claim that energy flows past a point with
a constant voltage of 0 that I have a problem.

> Take another look.

In the simulation they show voltage waves. No problem.

Thanks for the rundown on "light ion" plasmas, plasma propagation, and moving-wall waveguides. I only have one remaining question.

Do the "vibrations" of electromagnetic waves you referred to in your previous post have another name?

==========

Dear Pieter, pleased to meet you.

The first thing to say is that the impedance of the short length of coax line between antenna and receiver has very little to do with the unbalanced-to-balanced transformer between coax and receiver input. The coax is just a short length of wire between antenna and receiver with a relatively small capacitance between the the wire and ground.

To design a transformer more information is needed. But whatever it is it will be a very easy to make. All you will need is a small ferrite ring and a length of thin enamelled copper wire.

What range of frequencies would you like your receiver to cover? Long-waves, medium-waves, short-waves or VHF FM

What sort of antenna are you using? Is it a simple vertical whip connected directly to the coax.?

Is anything connected betwen the antenna and coax? How high is the whip. Is the height of the whip adjustable.

Please provide more information and the number of turns of wire on what size ring can then be decided.

I second the notion for a Radio Shack discone antenna. It's just what you're asking for unless you want directivity & gain to focus on areas. In that case, I recommend a log-periodic dipole for VHF/UHF.
In the latter case, it depends on your geographic position and interests. If you're in the burbs and interests lay in the town 10 miles away, then you'd turn the LPD array toward town at it'd be better. Just food for thought.
Maybe if you're very serious, you could eventually put both in the attic. An antenna switch and a rotator... Bam! The best of both worlds.

That was my whole point, Ian. Richard seems to believe those thing
are specifiable. I assumed his belief for the purpose of seeing
where it leads. Even if one can somehow know those things, they
still cannot be proven by measurements, or so it seems to me.

Why would you choose to handicap your knowledge by not looking inside
the black box? Are you playing silly games or searching for knowledge?
Who is prohibiting you from looking inside the box and thus contributing
to the ignorance in the world?

>>There is NO physical discontinuity at the black box.
>
> Exactly, and people argue that it is inappropriate to claim that a
> reflection occurs at this interface.

Yes, it is inappropriate. There is nothing to stop the forward wave
from flowing into the black box and nothing to stop the reflected
wave from flowing out of it unless there's a physical impedance
discontinuity at the black box.

> And yet, in the symmetrical case where there IS a discontinuity,
> many are quite comfortable talking about the lack of reflections
> at the inteface.

It's not rocket science. I have an exact amount of money in my pocket.
If I don't know what that amount is, then I am ignorant. But all I have
to do to alleviate my ignorance is to count my money.

If you don't know whether there is a physical impedance discontinuity
or not, then you cannot know whether there are reflections or not.
Alleviate your ignorance by ascertaining whether there is a physical
impedance discontinuity or not. Or do as you have apparently done,
choose to remain ignorant. Either one is fine with me. Just realize
what you are doing.

If reflections exist, there's a physical impedance discontinuity somewhere.
Stop being lazy, locate it, and point to it. That's where the
reflections originate. All this stuff is knowable, but some choose to

remain ignorant or play silly mental masturbation games.

The source was an MFJ269, and as I mentioned, the external series resistor was 75 Ohms. I should try it with something like 1K. Coax was ~100 feet of 9913. My scope is only good to 100 MHz; so, I have to keep the frequency down.

BTW, I have met Ed Norton.

>

This is the correct answer, you just interpret it incorrectly.

The reflection coefficient is defined as the reflected voltage
divided by the incident voltage. Sure, the voltage is zero right at
the short, but there is a reflected voltage wave that moves back
towards the generator.

When you have a short, the phase is flipped 180 degrees, which is
exactly what the -1 means. Notice if you had a Zl=infinity, that the
RC would be +1, which would be full reflections INPHASE with the
generator, or in phase with the incident voltage wave.

It's very simple stuff, but many people don't understand this.

I want you to tell me the significance of the fact that the
normalized load impedance Zn=Zr/Zo does NOT have the same angle as Zr
because Zo is complex in the general case. And how this may make this
example incorrect for this discussion.

Hi Carter,

As long as the cards clearly list your call and a signal report as well as the details of the QSO, time date, band, mode, they should be acceptable for DXCC submission. Most folks submit 102 or so cards with the first submission, then if there is a problem with one card, they are still OK.

As for the HA5-350 card, it sounds like an SWL report rather than an amateur call. (As above, does it have QSO details of your QSO with the call listed?) Since you'll probably be having a field checker look them over, he or she can tell you if it is legit card. Another question for the checker is whether the ten year old cards have to go into the ARRL DXCC desk (but ARRL Divisional Hamfests will have League reps who can check them).

Good luck and good DX,

Bill, W4WNT

That's the whole point. By the conjugate formula RC is *not* -1. It is -1
with a phase angle. I agree it works for an open circuit, since you can
divide both sides by Zl, and anything divided by infinity is 0

If you have a $30 preselector/amplifier between the antenna and radio that
will make a HUGE difference in signal strength and if you do there's not
much you can do to significantly improve reception by modifying the antenna.
The exception is, the higher the better.

4634. Complex line Z0: A numerical example

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 01:44:54 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vl2kp2cdlork04@corp.supernews.com>
Source record: 109177
Body handling: HTML body converted to readable text

Here's a numerical example of a transmission line having a complex Z0, terminated with a load impedance causing the magnitude of the reflection coefficient to be greater than 1.

For a transmission line, I chose an approximate model of RG-58. I say approximate, because the conductor loss doesn't include the shield loss, something I haven't yet accurately included in my calculations. But the calculated loss and Z0 are at least in the ballpark of what you'd see with a real transmission line. At a frequency of 10 kHz, my "pseudo-RG-58" shows a Z0 of 68 - j39 ohms (78.39 at an angle of -29.84 degrees), and velocity factor of 0.492. I chose to analyze a system with one wavelength of the cable for convenience in doing the calculations. One wavelength of the cable is 14753 meters, and the matched loss of that length is 31.60 dB. Other characteristics are:

Loss constant alpha * length = 3.637
Propagation constant beta * length = 6.283

For a load, I chose 10 + j50 ohms (50.99 at an angle of 78.69 degrees). This produces a voltage reflection coefficient of 1.349 at an angle of 115.1 degrees.

Again for calculational convenience, I chose a forward voltage at the input end of the cable of 1000 + j0 volts. All the results can be scaled if wished for any other value.

The following uses the notation in _Reference Data for Radio Engineers_:

fE1 = Forward voltage at input end of the line
rE1 = Reverse voltage at input end of the line
E1 = Total voltage at the input end of the line
delta = angle of Z0
psi = half the angle of the reflection coefficient
rho = magnitude of the voltage or current reflection coefficient

And, I'll use Gv for the complex voltage reflection coefficient = -Gi, where Gi is the current reflection coefficient. Positive reflected current rI is toward the load. Positive average "reverse power" is toward the source. "<>" denotes an average value.

ax = alpha * length
bx = beta * length

For current, I is substituted for E, and for the load end, 2 replaces 1. All voltages, currents, and impedances are complex phasors unless enclosed in absolute value signs (| |). Values so enclosed are

magnitudes only. All currents and voltages will be RMS. Steady state is assumed.

Because I've chosen an even wavelength, and calculations are done only for the ends of the line, the complex propagation constant gamma is replaced by its real part alpha in all equations below. If other line lengths are used, or calculations done for intermediate points along the line, beta will have to be included.

When written in polar notation, A /_ B means "A at an angle of B degrees".

Calculated values are:

fE1 = 1000 /_ 0
fE2 = fE1 * exp(-ax) = 26.34 /_ 0
rE2 = fE2 * Gv = 35.53 /_ 115.1
rE1 = rE2 * exp(-ax) = 0.9361 /_ 115.1
fI1 = fE1/Z0 = 12.76 /_29.84
fI2 = fI1 * exp(-ax) = 0.3360 /_ 29.84
rI2 = fI2 * -Gv = 0.4533 /_ -35.06
rI1 = rI2 * exp(-ax) = 0.01194 /_ -35.06

These values allow us to calculate all the voltages, currents, impedances, and powers at the ends of the line.

E1 = fE1 + rE1 = 999.6 /_ 0.0486
I1 = fI1 + rI1 = 12.77 /_ 29.78
E2 = fE2 + rE2 = 34.11 /_ 70.65
I2 = fI2 + rI2 = 0.6689 /_ -8.033

A quick check shows that the impedance looking into the input end of the line = E1/I1 = 78.28 /_ -29.73, very nearly the line's characteristic impedance. This should be expected, considering the line loss. At the output end, E2/I2 = 50.99 /_ 78.68, which is the load impedance as it should be.

The average power into the line = E1 * I1 * cos(theta), where theta = the angle of E1 - the angle of I1 =>

= 11080 watts

The average power out of the line at the load end =

= 4.477 watts

So the line loss is 10 * log(11080/4.477) = 33.94 dB. This is a little greater than the matched loss of 31.60 dB because the line isn't matched.

You must have noticed that the reflected voltage rE2 is greater in magnitude than the incident voltage fE2 at the load. This doesn't violate any law of conservation of energy, however -- examples abound of passive circuits that effect a voltage step-up. But, likewise, the reflected current exceeds the forward current.

Some posters on this newsgroup are very fond of looking at average powers calculated from various waves, so let's do those calculations:

= fE1 * fI1 * cos(delta) = 11070 watts
= rE1 * rI1 * cos(delta) = 0.009695 watts

Not surprisingly, ~ , so we can't tell much from these. At the load end,

= 7.677 watts
= 13.97 watts

Aha! you say, we've created power!

Well, no we haven't. If you'll recall from the earlier calculation of and , we've lost power, not created it. But the "forward power" minus the "reverse power" is a negative number! Yes, it is. But if you bother to go through the math, you'll find that the actual, net power equals the difference between "forward" and "reverse" power only if Z0 is completely real (or one other special case). The general formula for total power in terms of "forward" and "reverse" power is:

= - + rho * exp(-2ax) * 2 * sin(2bx - 2 * psi) * sin(delta)

delta is the angle of Z0, so the extra term on the right becomes zero only when Z0 is completely real. Of course, a purely imaginary Z0 (angle of +/- 180 degrees) would have the same effect, but that can't occur in a real cable. Interestingly, the right hand term also goes to zero when 2bx - 2 * psi = n * 180, where n is any integer including zero. That means that, even when Z0 is complex, the average total power will be the difference between fP and rP at particular points along the line, or at the input end of particular line lengths.

One of the very important things this example illustrates is the danger of drawing conclusions from the average powers in the individual forward and reverse voltage and current wave components. Somewhere, somehow, you've also got to account for the power in that extra term -- a power that comes and goes along the cable! I challenge anyone who's fond of this kind of analysis to explain the component powers on this line.

This analysis has produced a self-consistent set of voltages, currents, impedances, and (net) power. No physical laws were violated. If anyone thinks this analysis or its conclusion are in error, I invite you to do a comparable analysis, starting only with the same assumed transmission line and load.

I've also run a similar analysis of a hypothetical lossless cable with the same Z0. Such a cable, as far as I know, can't be constructed. But if there's enough interest I'll be glad to post that also.

As always, corrections are solicited and welcome.

Roy Lewallen, W7EL

4635. Question about attenuators ...

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 01:54:24 UTC
From: Doug McLaren <dougmc@frenzy.com>
Message-ID: <kzc4b.21898$_B.1192660@twister.austin.rr.com>
Source record: 109178

I'm pretty new to all of this, so if this is a silly question forgive me :)

I thought I'd go ahead and make a 2m Yagi antenna so I can give transmitter hunting a try. (The plan I'm using is made of PVC pipe and 1" tape measures ... simple enough.)

The other thing you usually need is an attenuator, to cut the power when you get close. I've got instructions for one of these too, and it's pretty simple -- just a bunch of resistors and double throw switches to activate each stage, all in a shielded box.

The values of the resistor are given without explanation, but I'm sure those values were chosen to 1) attenuate the signal by the desired amount and 2) maintain the antenna/radio's impedance of 50 ohms. (I guess I could verify this with a little math if I felt the need ...) With about 5 stages, the total cost of parts is $30-$40 at Radio Shack.

Since you're not going to be transmitting through this attenuator anyways (it would just release the magic smoke) then why is it important to keep a good SWR ratio? Couldn't you just take a variable resistor (with an audio/logarithmic taper) and put it in series or parallel (which exactly depends on it's value) with the antenna input, and then adjust as needed until you have a sutiable signal level again?

Or would the messed up SWR ratios actually make the antenna not directional anymore or something like that?

(http://members.aol.com/homingin/index.html has lots of stuff on transmitter hunting, but no answers to this question. The offset attenuator seems good, however :)

Source record: 109179

If you do the attenuation in a single line to your receiver, rather than in feedlines for individual elements of an array, it won't have any effect on the antenna's pattern or other properties.

There are quite a few good reasons for having an attenuator maintain a match -- it makes it possible to have a predictable and repeatable amount of attenuation, it won't disturb other cascaded objects like filters or amplifiers, etc. But for your purpose, a variable resistor should be fine. The only problem you might have is that the amount of attenuation you can get will be limited by the capacitive coupling across the resistor. You could use two pots, or a ganged pot (with one section connected so its resistance increases when the other decreases), with one in series and the other across the line on the receiver side, to increase the attenuation range.

4637. Re: Purchasing Ferrite Cores for Balums

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 02:54:19 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vl2or7t41b3f09@corp.supernews.com>
Source record: 109180

Fair-Rite material type 43 is good for most baluns. It's available in a large number of core sizes. With other manufacturers, look for material with initial permeability of around 750. If you're not running more than a couple of hundred watts or so, you can get more impedance for fewer turns with one of the 70-series ferrites. This ferrite can get too hot, though, if you run a lot of power. If type 43 overheats, one of the 60 series like 61 will have less loss. It also has considerably lower impedance, though, so you might have trouble getting an adequate amount for the balun to be effective.

Amidon Associates has long been a source for small quantities of ferrite cores. I'm sure there are a number of others, which a web search should reveal.

Not in my house. The water main coming in is plastic. Yet the
electrical code requires me to ground to the meter fitting which is
the only metal in the system. It has plastic going out both sides.

I have to ground to the gas main which is plastic coated and doesn't
reach ground potential until it reaches the main on the other side of
the road. Of course all this ties to the electrical system ground
which is several 8' ground rods. about 8' apart.

Source record: 109182

Jack Belrose, VE2CV did considerable research and experimenting with OCF dipoles some years ago. Some of his work was published in QST. One of the conclusions he reached was that it's awfully hard to keep the common mode RF off the feedline to the shack.

4640. Re: A Subtle Detail of Reflection Coefficients (but important to know)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 03:00:50 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vl2p7f8pijhp12@corp.supernews.com>
Source record: 109183

It's often noted in texts that SWR is really a meaningless measure when applied to lossy lines. So I wouldn't unduly worry about strange SWR numbers for very lossy lines. Take a look at the analysis I just posted on another thread, which gives voltages, currents, impedances, and powers for an example case, and see if you can find anything wrong with it. The calculation used for reflection coefficient is based on its definition, namely reflected voltage divided by forward voltage. That agrees with all the transmission line and electromagnetics texts I have, which is getting to be quite a number now.

> Tam/WB2TT

I've looked at the 9 pages you sent me, and I'm not certain what to
tell you.

They say, "the fact that the rho may exceed unity on a dissipative
line does not violate a condition of power conservation (as it would
on a lossless structure)."

On the one hand, I give them creedence for addressing the
concept...it's what i've been saying all along.
However, they don't explain why a lossy line can INCREASE the
reflected power! The lossless line would not attenuate the reflected
wave at all!

They also mention that the normalized load impedance Zn=Zr/Zo does
NOT have the same angle as Zr because Zo is complex in the general
case. This may or may not make their example moot.

And i don't trust their Smith Chart extended out to 1+sqrt(2) for
a dissipative line. Maybe for an active network, but not a passive
one.

Also, they go from equation 5.12 to 5.13 without showing us how
they got there. Perhaps they just copied it out of another book and
used the formula incorrectly.

Certainly text books can disagree, just as the "experts" often do.

Maybe this book is hard to find because it's out of print because
nobody trusted it.

Doug:

To add to what Roy says, I have been able to only get 20 to 25 dB total attenuation at VHF with a single pot. And, the effect he overlooked is that unless you use the exact same electrical length cables, the attenuation will be different for every other configuration. So, if you develop a feel for knob position vs distance while hunting, it will change if you don't use exactly the same cables each time.

Haunt the swapfests and evilbay for attenuators. I have seen HP units go pretty cheap. Be careful of Kay brand, as they are known to have bad switches when they get old. If you want to learn the innards, that is a good way, rebuilding a Kay.

I think there was an old HP spectrum analyzer main frame with a model number like 853 which you can't give away these days. But, it has a nice rotary attenuator in it, if you find one. Then you just have to dispose of the rest of the box.

I don't see the problem. 100 /_30 degrees divided by 2/_5 degrees is 50/_15
degrees. Different phase angle. By general case they mean not the lossless
case.
>
> And i don't trust their Smith Chart extended out to 1+sqrt(2) for

4645. Should I run a Sky-wire loop?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 05:18:42 UTC
From: junkmail@altonillinois.com
Message-ID: <70729ae5.0308302118.56ac8c66@posting.google.com>
Source record: 109188

Should I run a Sky-wire loop?

I currently have a dipole hung by two trees about 30 feet off the ground.

I would replace the dipole and run the Skywire loop off the same trees, along with two more trees at the same height as the current dipole.

This antenna would only be used for receiving, and never for transmitting, the same for the dipole.

My question is, does anybody think it will make enough of a difference over the dipole to warrant running it?

I would also like to know what your views are on "grounding" either my current dipole, or the Sky-wire.

Currently, I have the coax center wire soldered onto one end of the dipole, and the braid soldered onto the other end. I was told that I should also ground the braid before it comes into the house and into the radio.

I do have a ground wire attached to GND screw on the back of the radio, going outside to a piece of copper pipe pounded into the ground. Is this enough, or do I need to also ground the braid, and if so, how? Will grounding help my reception, or decrease the noise on the line?

Thanks.

> The stock indoor seems fine for local VHF but not too good on the 800 mhz
> trunked system. How does the dicone work on the 800 mhz band?

Dunno. Never tried one. If it's outdoors or in the attic, it should be
better than a whip on a radio. It's kind of hard to get real good
performance from a vertical through that large a frequency range. You
might want to get a separate 800 mhz antenna. I've been trying
different antennas to try to improve cell phone signals. I made a
little 3 el yagi for cell phones out of 1/4 inch copper tubing.
"silver soldered plumbers delight" I bent the copper boom into an L,
so it can be held and pointed. I may try other antennas like corner
reflectors, bowties, etc, turned vertical for cell phone use. If you
are listening to trunked systems , you may need a fairly omni antenna.
Maybe a collinear vertical or something. You could make one from coax
sections and stick it in a tube of thin PVC. MK

You reminded me of the sometimes tremendous difference between RF
ground and electrical ground.

Many years ago I had my station temporarily down in the basement when
I still lived with my folks. (bout 43 years ago) There was a storm
headed our way and I decided to disconnect the antenna and goround out
the station.

Well, when I grounded the transmitter (HT-37) by tying the coax to the
hot water heating system the signals on 20 actually got louder...I
didn't have much of an antenna to begine with. I thought I might as
well give it a try and actually worked a couple of South American
stations with the transmitter output tied to that 1" copper water
pipe. The ground terminal had a copper braid tied to it, but that had

to run out a window and tie to an 8' ground rod that was pretty much
in dry sand.

Good thing no one used the ahhh facilities while I was transmitting as
everything in the water system was hot.

4648. EZ Way tower sheared hinge pin conclusion(?)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 05:50:19 UTC
From: ddl@danlan.*com
Message-ID: <1156198@news1.IPSWITCHS.CMM>
Source record: 109191

For those who were interested in how it turned out (not that I'm sure the story is over):

I had some help from a contractor friend. He ground off the welds at the ends of the hinge plate and we were able to nudge the tower back into place; however, the pieces of the pin would not move after much hammering. We unbolted the hinge plate (which was remarkably easy considering the age of the bolts--why doesn't modern galvanized hardware hold up like that?) and took it back to his shop where he heated it with a big oxy/acetylene torch. The two pieces of pin eventually yielded to the heat and more hammering. Unfortunately, the pin appears to be a non-standard size between 5/8" and 3/4" (maybe a little more than 11/16"). A machine shop was able to turn down some 3/4" stainless rod, but it may be a bit too small and it isn't clear what stress it can take.

We brought the torch back to the tower, but after hours of heating, hammering, and oiling the piece of the pin in the central tube would not move. My friend was going to get a welder to cut off the tube and attach a new one but (and I wasn't actually there when this happened) he instead had the idea to slice off the ends of the tube and pin. This allowed the pin to come out. I cleaned out the carbonized lubricant as best I could, applied liberal grease, and put everything back together with the new pin. But now I'm a little worried about trying to tilt the tower:

-The central tube took a *lot* of abuse from the repeated heating and hammering. There are little beads of metal all over it which I assume is re-melted zinc galvanization. It is probably bent a bit as well.

-Because the central tube is now about 3/8" shorter than it was, a lot of the pin is exposed and the forces are no longer as close to shear.

-Because the pin isn't quite as big as the old one and the tower isn't perfectly balanced one side of the hinge plate is down about 1/8" making the tower a bit off plumb. The bottom of the tower is pressing against one side of the bottom bracket where it used to be centered.

-I have no idea how strong the new pin is.

So, everything is fine for now as the stress on the hinge is minimal when the tower is up. But I'd like to get somebody to look at it before I try to tilt and expose the hinge to a few thousand pounds of force...

4649. Extend range of wireless motion sensor

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 06:22:12 UTC
From: Ivan H <ivan_hendricks@hotmail.com>
Message-ID: <4r43lvk976h0ijde4481g06e94gnqn84sr@4ax.com>
Source record: 109192

I just bought a 400 ft wireless motion sensor and cannot get the distance I want (big suprise :)). Anyway, I have read a lot about directional antenas as well as cantenna's on newsgroups and websites when I was researching options for my home wireless network.

What I would like is a directional (beam) type antenna to see if I can go the full 400+ feet I really need to go. Could a cantenna or something of simular design work? I'm not an expert at radio or electronics, but I can follow directions. Any other suggestions would also be appreciated.

I have one of those 1000ft driveway sensors and could not get the range. Hooking up the receiver to my old television antenna, which I don't use anymore due to DISH, worked like a charm. I tried the same idea and it seemed to work at first with a dipole antenna connected to the transmitter and receiver connected to the tv antenna, but then stopped and never worked again at that range. Not sure why. It still works at closer ranges.

Thanks in advance.

Ivan

I don't believe transmitter output impedance is fundamentally
un-knowable... only that it is extremely difficult to measure in
practice. All the measurement techniques I've heard of seem to be
subject to either theoretical weaknesses or problems of practical
accuracy.

Fortunately, it's something we hardly ever *need* to know, so we can
work around it.

Don't deride so-called "black boxes" - they are a very important tool
for finding new knowledge.

If a problem can be solved without knowing what's in the box, you have
found a very powerful solution that will work for *anything* inside
there.

Such general solutions don't always exist; but if you make a habit of
opening "black boxes" when it isn't necessary, you never will find a
general solution - and that's guar-an-teed.

>Who is prohibiting you from looking inside the box and thus
>contributing
>to the ignorance in the world?

I don't believe that's quite what you meant to say, but unwittingly it's
true! Rejecting the "black box" as a useful thinking tool is indeed
"contributing to the ignorance of the world."

It still remains incomplete. The sign is needed to know Vr.

And, of course, the sign information was lost as soon as Vf and Vr
were converted to power. Leaving power out of the picture would
preserve this information. That you always convert to power and
discard this information seems inconsistent in light of your
comments below on always wanting the most information.

In practice, because one often does not know the implementation details
of the load or transmitter or ...

> Are you playing silly games or searching for knowledge?

Thinking of black boxes is an excellent tool to assist in the search
for knowledge. As a tool, it can help identify which information is
critical to a solution and which is not.

> Who is prohibiting you from looking inside the box and thus contributing
> to the ignorance in the world?

As a person searching for knowledge through thought experiments you
decide when to open the black box. Thinking of different content inside
the box which produce the same situations outside the box will help
you discover what is important and what is not.

Do consider adding this thinking tool to your toolbox. It is quite
powerful.

> >>There is NO physical discontinuity at the black box.
> >

> wave from flowing out of it unless there's a physical impedance
> discontinuity at the black box.

And yet you feel quite free to state that sometimes there is NO
reflection when there IS an impedance discontinuity. All I want
is some consistency.

If you wish to claim that there are no NET reflections at some
impedance discontinuities, then, for consistency, we should also
be able to claim that there are NET reflections when there is
no impedance discontinuity.

Goose and gander.

Seems to me there must be power in the light rings and none in
the dark rings. I am not sure where you get this notion of 'trapped',
but if there is no power in the dark rings, then the power from
the light rings is certainly not in the dark rings.

It was clear that you misunderstood what the -1 meant.

Ok, -1 with a phase angle. I believe it, if the Zo is complex.
The point is that the ratio of the reflected to incident voltage is
one, and has nothing to with the DC voltage measured at the short
itself.

-1 with a phase angle would simply be 180 degrees phase shift,
plus or minus and additional angle.

I want you to tell me the significance of the fact that the
normalized load impedance Zn=Zr/Zo does NOT have the same angle as Zr
because Zo is complex in the general case. And how the example you
sent me may make be incorrect for this discussion.

But they never explain WHY a lossy line can INCREASE the
reflected power! The lossless line would not attenuate the reflected
wave at all!

I don't trust their claims on this.

If you get more power reflected than you send into a passive
network, you are getting energy from nowhere, and are thus violating
conservation of energy.

Do some research, and you will never see an "extended Smith
Chart" for a passive network. Oh, certainly for a active device, for
stability circles and such, but passive networks can never have a rho
greater than 1.

Also the same conjugate formula in Les Besser's
RF Fundamentals I, and Kurokawa, and the 1992 ARRL
general Handbook, which has NO term for Zo reactance, so
it assumes a purely real Zo.

This page also has the correct general formula:

Excellent work William. You are also showing how
a rho>1 leads to ridiculous numbers for the equation:

SWR = (1 + rho)/(1 - rho)

The non-conjugate equation simply cannot handle
complex Zo.

> Something is wrong here that we are overlooking.

> What about it folks? How can we get to the bottom
> of this?
>
> Bill W0IYH

If you believe that there are theoretically no
reflections in a conjugate match, then with

Zl=50+j10 and Zo=50-j10,

the conjugate equation correctly cancels the reactances
giving no reflections, while the non-conjugate still
incorrectly gives a magitude (non zero) for rho.

Also the same conjugate formula in Les Besser's
RF Fundamentals I, and Kurokawa, and the 1992 ARRL
general Handbook, which has NO term for Zo reactance, so
it assumes a purely real Zo.

This page also has the correct general formula:

http://www.zzmatch.com/lcn.html

Reg,

Thanks for your reply. It is a "normal" car antenne meant to receive general AM/FM broadcasting. So as for the FM it will be somewhere between 80- and 110MHz. The antenne is about 1m long and has a kind of coil or spring near the bottom. It has 5.5 turns, 23mm diameter and a length of about 45mm. I guess this has to do with matching the antenna to the coax. A car radio just works fine but I also want to use it with an old (tube) radio. Not in a car but on the attic. You will understand that it is for experimental purposes. If only I want to receive general broadcasting, I just use a modern (transistorised) radio. I have a handfull of pink colored ferrite cores but I doubt they will be usefull around 100MHz. Nevertheless I hope I can get the core I need in the local electronics shop. You cannot be sure these days. They do not sell the 300 Ohm flat cable anymore. We're all cabled with 75 Ohm coax.

A Horizontal Loop will pickup less vertically polarized atmospheric noise. I am very satisfied with my 480 ft loop that is up 35 ft. For receive only, an ATU would not be necessary, but it will improve the signal strength at some frequencies.

My feedline is open line from the corner of the loop to the earth where there is a 1:1 current type balun. I connect the shield of the coax to a 8 ft ground rod. If your area is prone to lightning, I would install a polyphazer. The coax runs underground to the shack. The coax is only connected to the rig when I am actually using the antenna.

This reconfiguration is relatively inexpensive. Go for it and compare the results.

You lot will drive me to despair.

What's the problem?

You have just designed the PA.

You are familiar with its very simple internal
circuitry.

You have its component values, including the active
ones.

Hasn't it yet occurred to you engineering Ph.D's all
you have to do is calculate it.

Sewer kids in Rio have better arithmetical aptitudes.

==========

It is true the formula gives the greatest possible
magnitude of the reflection corfficient, Rho, for
any given value of the angle of Zo.

As t0 approaches -45 degrees, Rho approaches
1+Sqrt(2) = 2.414

As you must know, the formula is obtained by
differentiating Rho with respect to the angle of
Zo and then equating to zero.

It provides proof that values of Rho greater than
unity do exist. But a worship of mathematical logic
is not part of any religion on this newsgroup.

Source record: 109217

Let's start all over on this.

1. You have a transmission line of Zo= 1 - j1
2. Zo* = 1 + j1
3 Short the end of the line
4. By the classic formula RC= (0 - (1 - j1))/(0 + (1 - j1))
= -(1 - j1)/(1 - j1) = -1
5. By Besser's formula RC = (0 - (1 + j1))/(0 + (1 - j1))
which is (-1 -j1)/(1 - j1)
6. The above is SQRT(2)/_-135 / SQRT(2) /_-45 = 1/_-90
7. Note that RC has angle -90, not 180.
8. Reflected voltage is now (V+) x (1/_-90). This is in quadrature with V+,
not in opposition with.
9. This won't meet the boundary condition that (V+) + (V-) = 0
10. You can use a different phase angle for Zo if you like, but the only Zo
phase angle that will give you RC = 1/_180 is 0.

Walter,
It depends a lot on what type of feed line you use. If
you use coax to feed the loop, performance will probably
be about the same or worse than the dipole. If you use an
open wire or ladder line feed line through a tuner, you will
probably see ~some~ difference between the two antennas. How
much is anyone's guess. I like large loop antennas. I've
found that using ladder line and a tuner will make them usable
on more than one band and usually performs better than a dipole
used the same way (I don't have the best place to put up an
antenna to start with). Every installation is different so
what works great for me, here, may not work very well at your
location. Having said that, try the loop. If you don't like
how it performs, change back.

Ivan & Tom-

I've had a couple of old Heath GDOs over the years. I was never able to find a dip by coupling into the antenna's co-ax. I see that Ivan's article above contains the "secret" method I finally found that works - you have to short-circuit the feedpoint of the antenna and couple directly to the element.

The article above suggests that you can form a loop in the antenna wire to couple more tightly to the GDO. However, that would tend to introduce inductance which would interfere with the measurement. What I do is lay the coil next to the antenna element so the antenna wire is parallel with the GDO coil wire tangent.

For example, take a one meter wire or un-bent coat hanger. A GDO coupled to it should have a dip at 150 MHz. I expect there will also be a dip around 450 MHz, et cetera (odd harmonics).

Yes. Stay in CB where you belong.

Unless you have an interest in technical matters, which
will to a large extent remove any need to spend a lot of money,
then you don't have the makings of a Radio Ham anyway.

The stock indoor seems fine for local VHF but not too good on the 800 mhz trunked system. How does the dicone work on the 800 mhz band? >>

Bob-

A basic discone has about a ten to one frequency range. The latest version of Radio Shack's discone has a vertical element added so it can be used to transmit on the Six Meter Ham Band. The earlier version without the vertical element, was good from about 100 MHz to 1000 MHz.

The discone is intended for use with scanners. Even with the Six Meter element, it is probably the best choice readily available to cover all frequencies up to the 900 MHz Ham Band. You may be able to remove the element and see if it makes any difference at the higher frequency.

The other side of the coin is that a black box can be used to obscure the truth. It's easy to use a TDR to find out if the apparent steady-state short at the black box terminals is physical or not. But such an experimental act is prohibited by the steady-state religion. A large percentage of the black box examples on this newsgroup are designed to obscure, not enlighten. If obscuring is the goal, let's perform our black box experiments in total darkness to make it even more challenging for truth-seekers.

Is the old radio an AM, FM, or both? I'm not sure the 75/300 TV
balun is rated for 1 MHz operation.

Reg,

I am *not* a PhD, but, I can tell you what the problem is. You don't know what the transistor's Norton equivalent collector (drain) resistance is at DC, let alone RF. It is generally not on data sheets. They will often specify an "output impedance". This is a convenience for people who *think* they are doing conjugate matching. The real component of this has absolutely nothing to do with a particular device, outside of second order effects caused by series lead inductances.

Check out Motorola application notes AN282A, 721, and 1033. The following is a quote from AN1033:

"The output impedance of a microwave power transistor is usually defined as the conjugate of the load impedance required to achieve the desired performance. A typical output equivalent circuit is shown in Fig1. { Shows current source in parallel with Cout and resistor labeled <transformed load impedance>. From these two nodes there are inductor Lc and Lcom going to the output terminals}. The capacitor Cout is nearly equal to the collector - base capacitance Cob specified for the selected transistor. Lc is the inductance of the bond wire used to bridge from the collector metallization area to the package output lead, and Lcom represents the inductive effects of the common element bond wire"

"For correct operation of the transistor, the ultimate load impedance must be transformed to a real impedance across the current generator. This real impedance is determined by

RL = (Vcc - VCEsat)^2/(2Pout)

The load impedance presented to the package terminals will contain the real impedance at the current generator, transformed to a lower value by the low pass section formed by Cout and the parasitic inductances Lc and Lcom. Usually the reactive part of the load impedance is made inductive to tune out the residual capacitance of the device."

One of the other ap notes mentioned collector resistance to the extent that it is "high". This kind of analysis is not limited to transistors. For kicks, I calculated the load for an 813 tube, and got the same value as a book I was reading, which used a roundabout method. The other ap note also made a point of the fact that if you were actually conjugate matched, the efficiency could never be more than 50%.

The point was that Pref=0 and therefore, there is no sign to deal
with for rho=Sqrt(Pref/Pfwd). +0 = -0

> And, of course, the sign information was lost as soon as Vf and Vr
> were converted to power.

In the example case, Pref=0 and therefore rho=0. What difference does
the sign make when rho=0?

> Thinking of black boxes is an excellent tool to assist in the search
> for knowledge. As a tool, it can help identify which information is
> critical to a solution and which is not.

That's true, but refusing to open the black box when it is possible to
do so to gain knowledge is sheer nonsense for truth-seekers. OTOH, it
is a great tool for someone who is seeking to obscure the truth and
promote the steady-state religion at all costs.

> As a person searching for knowledge through thought experiments you
> decide when to open the black box.

Yes, and what is the person, who then objects to the opening,
searching for?

> Do consider adding this thinking tool to your toolbox. It is quite
> powerful.

It is in my toolbox but it does not dictate my attitudes toward
reality. If it is finally possible to open the black box in
order to ascertain the truth, I will certainly open it. Before
that, I will subject it to TDR experiments, something you would
no doubt object to since it is not "steady-state". With a TDR,
it is duck soup to prove that an open-circuit 1/4WL stub is
not shorted at the mouth of the stub.

> And yet you feel quite free to state that sometimes there is NO
> reflection when there IS an impedance discontinuity. All I want
> is some consistency.

I said there is no NET reflection at a Z0-match. I provided the
following s-parameter equation to illustrate that the two

reflections at a Z0-match will superpose and cancel each other.
b1 = s11*a1 + s12*a2 Do you understand the s-parameter equations?
If not, HP's AN 95-1 is available for download from the web.

> If you wish to claim that there are no NET reflections at some
> impedance discontinuities, then, for consistency, we should also
> be able to claim that there are NET reflections when there is
> no impedance discontinuity.
>
> Goose and gander.

I suggest you study and understand the difference between a logically inclusive statement and a logically exclusive statement. The difference lies in the use of the word "some" Vs "all". Above you performed a logical switcharoo when you went from "some" to an implication of "all". That is known in logic as an "argumentum ad absurdum".

Sometimes, there are NET reflections at a physical impedance discontinuity. If a single RF source signal exists, there are always component reflections at a physical impedance discontinuity.

Sometimes, there are no NET reflections at a physical impedance discontinuity because the two component reflections cancel. This is true of Z0-matched systems with reflections.

Sometimes, there are net reflections existing where there is no impedance discontinuity. They are the result of reflections at a physical impedance discontinuity somewhere else. Reflected waves are traveling waves. They travel from their point of origin to other places in the system.

Sometimes, there are no net reflections where there is no impedance discontinuity, e.g. a flat system.

Yes

> I am not sure where you get this notion of 'trapped',

:-) Good one :-) You say the power in a transmission line is trapped between the zero power points and cannot cross the boundary. The transmission line is virtually identical to the bright and dark rings in a light interference pattern.

> but if there is no power in the dark rings, then the power from
> the light rings is certainly not in the dark rings.

Point is, the energy in the bright rings is not trapped there. It continues to flow in a straight line. The bright rings and dark rings are the result of interference between two beams of light traveling in straight lines at the speed of light. The voltage-zero and voltage-maximum points on a transmission line are the result of interference between two waves traveling in straight lines at the speed of light. In the absence of a physical impedance discontinuity, there is nothing to change their momentum. Their momentum allows them to "coast" across a voltage-zero point.

Not taking sides here, just hopefully contributing something.

The s-parameters normalize voltages to the square root of Z0
such that the square of 'a1' is incident power normalized to
Z0=1.0. The standard Smith Chart is normalized to Z0=1.0. Thus
s-parameter quantities can be plotted directly on a standard
Smith Chart. The above equation looks as if Z0=1.0 for
normalization purposes. If 50 ohms is normalized to 1.0,
then Zn is probably Z1 also normalized to 50 ohms, i.e.
(Z1-Z0)/(Z1+Z0) = [(Z1/Z0)-(Z0/Z0)]/[(Z1/Z0)+(Z0/Z0)] =
(Zn-1)/(Zn+1) = s11. The 'n' in Zn may mean Z1 "normalized".

Please don't confuse usenet with ham radio. Except for a few really
bad apples (which also exist in CB) hams on the air are polite and
courteous and generally abide by "The Amateur's Code". That code
obviously doesn't exist on usenet.

Of course, but can you prove that impedance is what is "seen"
by the incident reflected waves? Dr. Bruene attempted it and
AFAIAC, didn't succeed because his ping frequency was different
from the operating frequency.

Well, I did get it working with a different dipole. Now my problem is when the antenna is connected to the motion sensor, it continuously trips the motion sensor. If I unplug it, it only trips when it senses motion. Could some sort of interference/noise received by the dipole be causing the unit to trip all the time? How could I solve this?

I know my questions are not specifically related to amateur radios, but I figured this would be the best place to find an answer as I am dealing with signal transmission and antennas.

Cheers,
Ivan

4697. Re: A Subtle Detail of Reflection Coefficients (but important to know)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 19:04:57 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vl4hn1lqe6f502@corp.supernews.com>
Source record: 109089

A few days ago I posted a derviation of the (non-conjugate) formula for voltage reflection coefficient on a transmission line. It required only a few assumptions:

1. That the voltage reflection coefficient is the ratio of reverse to forward voltage.
2. That the voltage at any point along the line, including the ends, is the sum of the forward and reverse voltages, and that the current is the sum of forward and reverse currents.
3. That the ratio of forward voltage to forward current, and the ratio of reverse voltage to reverse current, equal the characteristic impedance of the transmission line.

Given these assumptions, the derivation is a matter of straightforward algebra.

For those promoting some other formula for voltage reflection coefficient: Which of the above assumptions is false? What substitute assumption is true? And what's *your* dervivation? Remember, we're talking about transmission lines here, not a one- or two-port analysis with a "reference impedance" instead of a transmission line, and where there's no restriction that the total voltage and current are simply the sum of the forward and reverse components.

Number 1 is not always true for s11, the s-parameter reflection
coefficient.

> What substitute assumption is true?

For an s-parameter analysis, it's that s11 = b1/a1 when a2=0
Your definition above says that rho = b1/a1 no matter what
the value of a2. Some configurations have rho = s11 and some
don't.

There are differences between your transmission line analysis,
an s-parameter analysis, an h-parameter analysis, a y-parameter
analysis, or a z-parameter analysis. If they were all alike,
there would be no need for their separate existences. FYI:

s11=[(h11-1)(h22+1)-h12*h21]/[(h11+1)(h22+1)-h12*h21]

s11=[(1-y11)(1+y22)+y12*y21]/[(1+y11)(1+y22)-y12*y21]

s11=[(z11-1)(z22+1)-z12*z21]/[(z11+1)(z22+1)-z12*z21]

s11=Vref1/Vfwd1 when Vref2=0, i.e. Pref2=0

Any idea what kind of service I should be looking for? I could bring the base plate somewhere, but that isn't the part that I'm worried about. The real stress was to the center of the hinge that is welded to the ground post, so someone would have to come to my house to (re)build it. The local machine shop doesn't seem to be into this kind of thing. Maybe I need a millwright (old definition)?

What I always did, and I'm sure it was in the manual, was to wind a
few turns of hook-up wire and solder the ends to a coax connector. I
then plugged in the coil at the end of the coax, stuck the GDO coil
through the coil on the connector, and took a reading. I can't recall
that using that method ever mislead me. I think I even have that
little coil on a BNC out in the junkbox.

I sold the Eico GDO that I had for years. In 1999 I acquired a Millen
GDO in mint condition from an estate sale. I sold it on Ebay, but now
wish I had kept it.

4708. Comet VA30 (base loaded tri-band dipole 40/15/10)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-08-31 20:56:44 UTC
From: PA3HHO <billyrocksagain@hotmail.com>
Message-ID: <bitnon$783$1@reader1.tiscali.nl>
Source record: 109102

Hi OM's

Last year during a Dutch Ham fair I bought myself a Comet VA30. This is a shortened base loaded multiband dipole for 7/21/28 MHz. The manual that was included was Japanese. I was able to figure out the correct dimensions (depending on how you setup the antenna e.g. as a horizontal dipole or (3 x) vertical with one (3 x) radial per band.

The instructions about a capacitor that's supposed to be in parallel with the feedpoint is unreadable. I know that (heavily) shortened dipoles need some kind of adaption to get a VSWR of 1:1 @ 50 Ohm. Two caps (small ceramic disc type, probably in 100's of pF range) are included but I'm not sure which one to use. I've used one, the other, both and none, but VSWR is terrible on all three bands.

I know I can't expect micacles from a 2 x 9 ft dipole on 40 meters, but I should do OK on 15 and 10 I guess. Because of it's size it's ideal for on holidays but last one was no success at all. Anyone has any experience with this antenna and/or maybe has an English (German, French or Dutch OK too) manual for the Comet VA30?!

Thanks!

Rgrds, Pleun (PA3HHO)

You can speak of anything you want. But a transmission line analysis
including a tuner and reflected waves *IS* a two-port analysis at the
tuner. It *IS* a one-port analysis at the load. There's just no getting
around it. Your transmission line analysis resembles a Z-parameter
analysis of one-port and two-port systems.

==========

There's no difference between the two. If you produce the symetrical S-matrix for a length of transmission line, its 4 parameters contain complex hyperbolic functions like (Ro+jXo)*Cosh(A+jB) . . . . . where A is nepers and B is radians.

Whichever way you go, matrix-algebra or Heaviside, you perform exactly the same set of calculations and, not surpisingly, you end up with the same answers - provided Zo in one place only is not followed with an askerisk just to obtain another answer which is thought to be more preferable.

|
| But a worship of mathematical logic
| ...
| on this newsgroup.
| ...
|
====================
-
Dear Mr. Reg Edwards,
-
Thank you for your comment.
-
A.
For the formula:
Actually,
after ten days of revision of the book
"Transmission Lines" by R.A.Chipman, [Shaum's, 1968]
-a great book in general, not only on its subject-
and of the accompanying notes by yin,SV7DMC
-who in the Summer of 1995 checked all the material
and solved all the problems of the book-
I realized, at last, that:
-
The formula at page 137,
for the magnitude of Rho
as a function of its normalized impedance ZT/Z0,
produces as an image, a
[-135,+135] degrees "Packman".
-
Therefore,
every complex Z0 with argument t0

restricts the Packman
to a rotated "Half-moon"
with boundaries at
[-90-t0,-t0+90] degrees.
-
An application
of the condition |ZT/Z0|=1
-which is a result of differentiation indeed-
on each of the two mentioned boundaries,
results immediately to
the biggest of the two respective values:
-
Sqrt([1 + Sin(Abs[t0])]/[1 - Sin(Abs[t0])]).
-
But the last one
is always either equal to or greater than unity.
Thus for
t0=-45 degrees
it gives
1+Sqrt(2), indeed.
-
B.
For the newsgroup:
Yes, perhaps.
But please,
let me tell you that:
The newsgroup being
an insistent mathematical logic challenger,
finally becomes,
in this way,
a valued friend,
at least for us, down here.
-
Sincerely yours,
-
pez
SV7BAX

> (Zn-1)/(Zn+1) = s11. The 'n' in Zn may mean Z1 "normalized".

This is understood.

What is not is how one gets from:

Voltage R. C.= (Vr/Vi)e**(2*y*z)

where y=sqrt((R+j*omega*L)(G+j*omega*C))
and z= distance from load

To:

Voltage RC=(Z1-Z0)/(Z1+Z0)

And i have NO problems with the normalized formula,
AS LONG AS Zo IS PURELY REAL.

If Zo is complex, then Zo*/Zo is certainly NOT equal to
one!

I don't really trust this book too much, maybe that's why
it is out of print.

But the square of the MAGNITUDE of the Voltage RC is the power
RC.

They never tell us why, and i don't think a lossy line will
increase your chances of getting rho>1. In fact, i don't believe this
is possible with a passive network.

>

> >
> I think the math is the same as for a lossless line

What is not understood is how one gets from:

Voltage R. C.= (Vr/Vi)e**(2*y*z)

where y=sqrt((R+j*omega*L)(G+j*omega*C))
and z= distance from load

To:

Voltage RC=(Z1-Z0)/(Z1+Z0) for purely real Zo
or Voltage RC=(Z1-Z0*)/(Z1+Z0)

And i have NO problems with the normalized formula,
AS LONG AS Zo IS PURELY REAL.

If Zo is complex, then Zo*/Zo is certainly NOT equal to
one!

I don't really trust this book too much, maybe that's why
it is out of print.

E-Bay has them, but , these rigs are over 30 years old, and from company been out of business about that long, and they were TVI GENERATORS ! ! And there are better rigs (solid state, and much CLEANER !) out there quite reasonable !, Try yaesu (ft-620), also, kenwood made 6 meter ssb rig TS-600, SSB Engineering SB-50, and, then there are transverters for your low band xcvr! (all of these around $300-350) tho, I hate ICOM (never had one didn't self destruct!) but, they made several (biggest problem with these is replacement parts , never made many for them!) but, tubes have about had it (at power levels below 500 watts , IE 4x150-250, 8873-4-5, 3-400/500z, ect, even the 6146 getting hard to find new!) , but, you don't need great power, either-- from the voice of experience! (6 METER Q.R.P. W.A.S. , # 724)

It very simple, and no complicated math is needed to understand.
The port impedance does not change from when the incident power
is launched and when the reflected power returns, so the power will be
((Vrms)**2)/Zo). This should still hold if the Zo is complex, because
you will have the same load in both cases. If the RMS voltage
returning
is greater that the voltage you put in, you MUST have an active
device.

If you simply square the MAGNITUDE of the voltage reflection
ratio, you will get the power reflection ratio. So if the voltage RC
is greater than one, so will be the power reflection coefficient.

Understand that me and William E. Sabin didn't invent the
conjugate equation, it has been there all along.
You Reg, were the one who convinced me that the "normal" R. C.
equation
must be wrong for complex Zo.

Please look it up in any basic RF book: For a passive network,
0=<rho=<1. But the R. C. can never be more than one for a passive
network.

I challenge anyone to find a reflectometer calculator that shows
rho > 1.

Slick

If I use a Polyphaser lightning arrestor, that is grounded to a grounding rod, and hooked to the feed line, and the radio, will that do the same job as grounding the coax feed line braid?

or are we talking about two different grounding steps?

thanks for the help!!!
